Eleven muscles may be named as more or less distinct in the *spinirector* series of man; that is to say, there is one muscle, with ten divisions, making eleven. These are all *direct;* that is, they are longitudinal or vertical, on the whole and in almost every detail. Thus they run from spine to spine of vertebræ, from transprocess to transprocess of vertebræ, from ilium to ribs, from rib to rib, and thence to corresponding positions on the occiput. The muscular masses collectively lie on either side of the middle line of the vertebræ, as far outward as the crest of the ilium, the angles of the ribs, and the mastoid process of the skull. The series is *artificially* divisible into those sections which run respectively along the sacri-lumbar, lumbi-dorsal, dorsi-collar, and colli-capital regions; that is to say, which lie in the three intervals between these four bounds. In the loin the muscle is indivisible. In passing thence to the thorax it splits into three parts, lying parallel and running abreast. These three parts are: (1) from spine to spine of vertebræ ("spinalis dorsi"); (2) from lateral processes of vertebræ to lateral processes of vertebræ and adjoining parts of ribs ("longissimus dorsi"); (3) from angle of rib to angle of rib ("sacro-lumbalis"). Then division (3) splits in two, giving (4) the "accessorius ad sacro-lumbalem." This makes the four partitions, which are best displayed near the middle of the back, say opposite the eighth rib. Thence, in passing from the thorax to the neck, three partitions of the muscle continue on: the "spinalis dorsi" as the "spinalis colli;" the "longissimus dorsi" as the "transversalis colli;" the "accessorius" as the "cervicalis ascendens." Meanwhile, however, we meet, before leaving the thorax, with the pointed prolongation down upon the thorax of the three muscles which lie parallel with one another and run abreast to the head. These are the "biventer cervicis," the "complexus," and the "trachelo-mastoideus." Their thoracic origin is from transprocesses of vertebræ; therefore they are the prolongations of the "transversalis colli" and "longissimus dorsi" partitions of the whole muscle; they lie between the "transversalis colli" and the "spinalis dorsi et colli." Then they rapidly increase in bulk, especially the complexus, and finish the *spinirector* series by insertion in the occipital and mastoid regions of the skull. The series is simplest at its either end; it is most complex at the root of the neck, where good dissection will show no fewer than six bundles of muscle. These are, from the middle line outward, (1) spinalis colli, (2) biventer cervicis, (3) complexus, (4) trachelo-mastoideus, (5) transversalis colli, (6) cervicalis ascendens. This means that the three bundles coming down from the head onto the thorax are wedged between the three bundles going up from the thorax onto the neck.

The arrangement is really not difficult to learn, but the way it is usually described, with such names as we

have used in the foregoing paragraph, makes it almost impossible to remember. Accordingly we have invented a system of names which express their own meaning; and which are connected with one another in the same way that the muscles themselves are connected, as will be seen by the following diagram, where the names are printed in somewhat the same relative positions that the muscles themselves occupy:

Sacro-lumbalis.	Dorsi-spinalis	Colli-spinalis.	
	Lumbi-dorsalis	Dorsi-cervicalis	Biventralis. / Complicalis. / Trachelalis.
	Lumbi-costalis	Costi-costalis	Costi-cervicalis.

It will be observed that these names are each a single word, and that they uniformly end in *-alis*. This is a matter of such practical convenience that we have changed two very good words, "complexus" and "trachelomastoideus," into very dubious forms to make them correspond with the rest. Secondly, with the exception of the three occipital muscles of the series, where we retain the old names in a modified form, every name indicates the situation of the muscle it designates. Thirdly, the connections of the names are such that they indicate what divisions of the series are continuous with one another. Thus, *dorsi-spinalis* + *colli-spinalis* are the continuous series of slips along the spinous processes of the back and neck. Again, *sacri lumbalis* + *lumbi-dorsalis* + *dorsi-cervicalis* are the next series, running from the sacrum along the lumbar and dorsal to the cervical region, its divisions being lumbi-dorsal and dorsi-cervical. Once more, *sacri-lumbalis* + *lumbi-costalis* + *costi-costalis* + *costi-cervicalis* are together the outermost series which run from the sacrum along the ribs to the neck, broken into sets of slips in the lumbi-costal, costal, and costi-cervical portion of its extent.

The innervation of this whole series is regular and uniform, from *external* branches of posterior divisions of the spinal nerves. To this statement the complicalis offers an exception. There being no external branch of the posterior division of the first cervical nerve, the complicalis draws upon that nerve direct. But the muscle is chiefly supplied by the "great occipital," the internal branch of the posterior division of the second cervical nerve, and the size of the muscle accounts for that of the nerve. The muscle is, however, in part supplied in the regular way by external branches of cervical nerves. These facts clearly show it to be a compound muscle, quite worthy of its name; and we suppose that it represents in itself muscles even of different groups. The biventralis, for example, the least distinct part of the muscle in man, is very different in birds, resembling a collispinalis.

2. DEEP GROUP.

["Fifth Layer."]

Innervated by inner branches of posterior divisions of spinal nerves.

The muscles of this group are more distinct from one another than those of the superficial group, because they lie so deeply between the processes of the vertebræ and the ribs as to be for the most part broken up in passing between successive segments of the trunk, much as the intercostals are. They also differ from the superficial group and resemble intercostals again, in being for the most part *oblique;* that is, they connect a given process of one vertebra with a different process of another vertebra, or with a rib. Their serial character is quite uniform from sacrum to axis, but is modified, in the thoracic and cervical regions, by the presence of "semispinales" in the thoracic region, by the occurrence of "rotatores" and "levatores," and, especially between the axis, atlas, and occiput, by special provision for the movements of the head. The innervation of the posterior recti and obliqui of the head is also peculiar, owing to the special character of the first cervical nerve which supplies these muscles. We may therefore divide the Deep Group into two subgroups, to which a recognizable third may be added for the peculiar coccygeal condition of man.

(*a*) *Suboccipital Subgroup.*

Innervation mainly by suboccipital nerve.

1. **Atlanti-rectus.** ["Rectus capitis posticus minor."]
2. **Axi-rectus.** ["Rectus capitis posticus major."]
3. **Atlanti-obliquus.** ["Obliquus capitis superior."]
4. **Axi-obliquus.** ["Obliquus capitis inferior."]

The first two of these muscles are modified interspinales, passing from the spiniprocesses of the atlas and of the axis, respectively, to the supra-occipital bone, which corresponds to the spiniprocess or neural spine of an ordinary vertebra. The last two muscles are modified *semispinales* or *fidispinales*, since they connect a transprocess with a spiniprocess; the *atlanti-obliquus* passing from the transprocess of the atlas to the supra-occipital bone, the *axi-obliquus* from the same point to the spiniprocess of the axis. Besides their regular innervation they draw upon the next cervical nerve, the "great occipital," to some extent.

(*b*) *Vertebral Subgroup.*

Innervation by internal branches of posterior divisions of spinal nerves.

5. **Semispinales.** ["Semispinalis dorsi et colli."]
6. **Fidispinalis.** ["Multifidus spinæ."]
7. **Rotispinales.** ["Rotatores spinæ."]
8. **Supraspinales.**
9. **Interspinales.**
10. **Transpinales.** ["Intertransversales."]
11. **Costispinales.** ["Levatores costarum."]

The arrangement is here very simple and regular. The basis of this system of musculation is the oblique set of fibres called the "multifidus," connecting the transprocess and artiprocess of a vertebra with the lamina and spiniprocess of some vertebra higher up. The more superficial the fibres the more vertebræ they pass by, and thus the *semispinales*, in the thoracic and cervical regions, are seen to be but superficial slips of the *fidispinalis*, and, similarly, the *rotispinales*, peculiar to the thoracic region, are but the deepest slips of the *fidispinalis*, passing only from one vertebra to the next. The *costispinales* (the so-called "levatores costarum"), also peculiar to the thoracic region, are simply the prolongation of the multifid system onto the ribs. The remaining muscles are the slips which directly connect spiniprocesses with one another and transprocesses with one another. The innervation of this whole group is regular, except that the most lateral or superficial slips may attract some supply from outer rather than inner branches of the nerves.

(*c*) *Caudal Subgroup.*

12. **Coccygerector.** ["Extensor coccygis."]

When any muscle is found on the back of the stunted coccyx of man, it is the vestige of epaxial caudal muscles which, in some animals, are as numerous, distinct, and even as bulky as those of other parts of the spinicolumn. The human remnant represents all of these, and therefore can hardly be brought under any of the foregoing categories. It appears most like a prolongation of the *spinirector*, and to that extent belongs with the spinirector series.

B. HYPAXIAL AXIAL MUSCLES.

Innervated by anterior divisions of spinal nerves or their equivalents; and not appendicular.

There is little intrinsic difference in the whole series of hypaxial muscles of the trunk, their innervation being continuously derived from anterior divisions of spinal

nerves, or, as in the head, by motor cranial nerves which are the equivalents of anterior divisions of spinal nerves. Unlike the disposition of the epaxial muscles of the back, however, the conformation of the parts enables us to group these muscles into the several obvious "regions" of the head, neck, chest, belly, and perinæum.

The first and second (olfactory and optic) nerves, being purely sensory or æsthesodic, have no voluntary muscles attached to them.

(The intrinsic involuntary musculation of the eye (iridian and ciliary) is derived from filaments of the nasal branch of the ophthalmic division of the trigeminus, together with filaments from the ophthalmic ganglion of the sympathetic.)

II. THE MUSCLES OF THE HEAD.

1. ORBITAL GROUP.

Innervation by the third, fourth, and sixth cranial nerves.

(a) Oculi-motor Subgroup. Third nerve.

1. **Palpebralis.** ["Levator palpebræ superioris."]
2. **Supra-rectus.** ["Rectus superior."]
3. **Infra-rectus.** ["Rectus inferior."]
4. **Intra-rectus.** ["Rectus internus."]
5. **Infra-obliquus.** ["Obliquus inferior."]

(b) Trochlear Subgroup. Fourth nerve.

6. **Supra-obliquus.** ["Obliquus superior."]

(c) Abducent Subgroup. Sixth nerve.

7. **Extra-rectus.** ["Rectus externus."]

These muscles lift the eyelid and roll the eyeball about.

2. MASSETERIC GROUP.

Innervated by the fifth cranial nerve (motor filaments of its infra-maxillary division).

1. **Temporalis.**
2. **Masseter.**
3. **Ecto-pterygoideus.** ["Pterygoideus externus."]
4. **Ento-pterygoideus.** ["Pterygoideus internus."]

These are muscles of mastication; they move the lower jaw upward and sideways. (For mylohyoideus and predigastricus muscles, also innervated from the *fifth nerve*, see beyond.)

3. CAPITI-CERVICAL GROUP.

Innervated by the seventh cranial nerve (the facial).

The panniculus carnosus or platysma myoides and its subdivisions, being the cutaneous muscles, or muscles of expression—*innervated by the facial nerve*—(with certain exceptions noted).

A. Cranial Region.

1. **Occipito-frontalis.** [Primary innervation normal, by the *facial nerve*, to anterior belly of the muscle; secondary innervation, to its posterior belly, by the *occipitalis minor*, from the *cerviciplex*.]

This muscle moves the scalp to and fro.

B. Facial Region.

(a) Aural Subregion.

2. **Attollens.** [Innervation irregular, by the *occipitalis minor*, like posterior belly of occipito-frontalis.]
3. **Attrahens.**
4. **Retrahens.**

These muscles move the ear up, to and fro.

(b) Ocular Subregion.

5. **Orbicularis.** ["Orbicularis palpebrarum."]
6. **Superciliaris.** ["Corrugator supercilii."]
7. **Tarsalis.** ["Tensor tarsi."]

These muscles shut the eyelids and wrinkle the skin of the forehead. The orbicularis is the sphincter of the eye.

(c) Nasal Subregion.

8. **Pyramidalis.**
9. **Compressor.** ["Compressor nasi," and "Compressor narium minor."]
10. **Depressor.** ["Depressor alæ nasi."]
11. **Post-dilatator.** ["Dilatator naris posterior."]
12. **Pre-dilatator.** ["Dilatator naris anterior."]

These muscles move the nose about, acting especially upon the nostrils.

(d) Oral Subregion

13. **Oscularis.** ["Orbicularis oris."]
14. **Buccinator.**
15. **Nasi-labialis.** ["Levator labii superioris alæque nasi."]
16. **Supra-labialis.** ["Levator labii superioris proprius."]
17. **Canini-labialis.** ["Levator angulæ oris."]
18. **Zygo-labialis.** ["Zygomaticus minor."]
19. **Malari-labialis.** ["Zygomaticus major."]
20. **Risi-labialis.** ["Risorius."]
21. **Anguli-labialis.** ["Depressor anguli oris."]
22. **Infra-labialis.** ["Depressor labii inferioris."]
23. **Menti-labialis.** ["Levator menti, or labii inferioris."]

These muscles move the lips, cheek, and chin. The buccinator is the sphincter of the cheek. The oscularis or kissing-muscle puckers the mouth, and is the sphincter of the lips. The labial muscles pull the lips in every direction. Those above No. 20 move the upper lip; those below No. 20, the lower lip. This set radiate from the mouth in a half-circle, from the nose around by the ear and thence down to the chin, in the order above given.

C. Cervical Region.

24. **Platysma.** ["Platysma myoides."]

This muscle wrinkles the skin of the neck and breast and indirectly lowers the jaw. It blends with all the muscles of the oral subregion.

D Tympanic Region.

25. **Stapedius.**
26. **Incudius.** ["Laxator tympani."]
27. **Malledius.** ["Tensor tympani."]

These muscles move the bonelets of the ear. No. 26 is improperly called a muscle, and likewise it is called incudius because it is not inserted in the incus. It may seem abrupt to pass from the platysma, a muscle of the skin of the neck, to the stapedius, a muscle of the tympanum. But the *facial nerve* here proves a safe guide. For the tympanum is primitively an infolding of the skin of the neck, and leads us through the Eustachian tube to the next group of muscles. Muscles of the tympanic subregion derive secondary innervation from other sources than the facial, as would be expected from their immediate position and transitional character between cutaneous and palatal regions.

(For stylohyoideus and digastricus, innervated from facial in part, see beyond.)

[The eighth cranial nerve, auditory, being purely sensory, has no muscular connections.]

4. PALATO-PHARYNGEO-LARYNGEAL GROUP.

Innervated by the ninth, tenth, and eleventh cranial nerves: sensory, sensori-motor, and motorial (motor influence supposed to be from the eleventh).

The innervation in this group is very complex, especially in the palatal subgroup, which is supplied largely by the *facial* (through branches from the *otic* and *sphenopalatine sympathetic ganglia*), and to that extent the group belongs to the preceding one. At least one muscle of the palatal subgroup (the tensor of the palate) may even get some innervation from the infra-maxillary divi-

sion of the *fifth*. But the regional relation of the muscles of the soft palate make it most convenient, if it be not also most natural, to bring them under this head.

(*a*) *Palatal Subgroup.*

1. **Uvularis.** ["Azygos uvulæ."]
2. **Palati-levator.** ["Levator palati."]
3. **Palati-tensor.** ["Tensor palati," or "Circumflexus."]
4. **Palati-glossus.**
5. **Palati-pharyngeus.**

[Nos. 1, 2, 4, 5, < *Meckel's ganglion*, < *facial*. No. 3, < *otic ganglion*, < *facial*; also ? < *infra-maxillary nerve*. No. 5, also ? < *pneumogastric*.]

These muscles move the soft palate, including the pillars of the fauces.

(*b*) *Pharyngeal Subgroup.*

6. **Stylo-pharyngeus.**
7. **Supra-constrictor.** ["Constrictor superior."]
8. **Medi-constrictor.** ["Constrictor medius."]
9. **Infra-constrictor.** ["Constrictor inferior."]

These muscles lift and squeeze the pharynx. The palatal and pharyngeal muscles are scarcely "voluntary" or under control of the will.

(*c*) *Laryngeal Subgroup.*

10. **Thyro-glottideus.** ["Thyro-epiglottideus."]
11. **Supr-aryglottideus.** ["Aryteno-epiglottideus superior."]
12. **Infr-aryglottideus.** ["Aryteno-epiglottideus inferior."]
13. **Triticeo-glossus.**
14. **Arytenoideus.**
15. **Post-arytenoideus.** ["Crico-arytenoideus posticus."]
16. **Pre-arytenoideus.** ["Crico-arytenoideus lateralis."]
17. **Thyro-arytenoideus.**
18. **Crico-thyroideus.**

The laryngeal are involuntary muscles, like the pharyngeal, but there is no harm done in naming them here. Nos. 10, 11, 12, whose names end in "-glottideus," go to the epiglottis. No. 13, in "-glossus," goes to the tongue. No. 14, the only muscle not paired, is the only one whose name is not compounded of two words. They are innervated by the inferior or *recurrilaryngeal* nerve from the pneumogastric, excepting No. 18, the crico-thyroideus, which is supplied by the external branch of the superior laryngeal branch of the pneumogastric; in a word, by the *cricolaryngeal* nerve.

5. GLOSSO-HYOID GROUP.

Innervated by the twelfth cranial nerve.

The muscles of the tongue and hyoid bone are well marked by their motor nerve, the *hypoglossal*, and its descending loop communicating with the cerviciplex, but the motor influence of the *facial* is here, as nearly everywhere else in the head. The intrinsic muscle of the tongue, the lingualis, is affected by the facial through the *tympani-chordal* nerve; and the stylo-hyoideus and post-digastricus are innervated directly by the facial. But the stylo-hyoideus often or usually has a branch from the *hypoglossal*, showing its proper relation to this group. The mylo-hyoideus and pre-digastricus, forming the floor of the mouth, have attracted their nerve-supply from the *infra-maxillary* branch of the *fifth*.

(*a*) *Glossal Subgroup.*

1. **Lingualis.**

From facial, through tympani-chordal.

(*b*) *Mylo-hyoid Subgroup.*

2. **Mylo-hyoideus.**
3. **Pre-digastricus.** ["Anterior belly of the digastricus."]

These muscles floor the mouth. Innervation from infra-maxillary > infra-dental > mylo-hyoid nerve.

(*c*) *Temporo-hyoid Subgroup.*

4. **Post-digastricus.** ["Posterior belly of digastricus."]
5. **Stylo-hyoideus.**

These muscles lift the hyoid apparatus. Their innervation is partly from the *hypoglossal*, chiefly from the *facial*.

The "digastricus" is a very remarkable muscle, and there is reason to think that it occurs in a highly specialized or even anomalous condition in man. There is no "anterior belly" in many animals, and the muscle supposed to answer to the posterior belly may go, as in birds, to the angle of the lower jaw, having nothing to do with the hyoid bone. Its innervation in man, from two different sources, and neither of these the *hypoglossal*, favors our view that it represents two distinct muscles, neither of which, very probably, belong to the glosso-hyoidean group. Though we keep it here for the present, we divide it into *pre-digastricus* and *post-digastricus*, associating the former with the *mylo-hyoideus*, the latter with the *stylo-hyoideus*.

The "digastricus" is still further anomalous in that its so-called anterior belly perforates another muscle, the stylo-hyoideus.

(*d*) *Supra-hyoid Subgroup.*

6. **Stylo-glossus.**
7. **Hyo-glossus.**
8. **Genio-hyoglossus.**
9. **Genio-hyoideus.**

These four muscles, like the four preceding, lift the hyoid apparatus; and they lower the jaw.

(*e*) *Infra-hyoid Subgroup.*

10. **Thyro-hyoideus.**
11. **Sterno-thyroideus.**
12. **Sterno-hyoideus.**
13. **Omo-hyoideus.**

These four muscles lower the hyoid apparatus and, with it, the jaw. This subgroup and the last are very fine ones, making up for the difficulty about the others. Down to No. 10, inclusive, the innervation is direct from the *hypoglossal*; then it comes from the communicating loop of the *cerviciplex*. With the last of this group, the omo-hyoid, we first find a muscle passing to insertion in a bone of the fore limb, pointing the way to consider the sterno cleido-mastoid and trapezius as muscles of the anterior extremity.

Of these thirteen muscles, throwing out the lingualis, which has no notable bony attachment, leaves twelve, all of which attach to the hyoid bone. These twelve divide into three groups of four each, one of these groups subdividing in two. Thus there are four infra-hyoid muscles, four supra-hyoid muscles in one group, and four more in two groups—a regularity of disposition which may help one to remember them.

(To be continued.)

PROFESSOR NATHANIEL LIEBERKÜHN.—In the correspondence from Berlin which appeared in our issue of June 18th, it was stated that the late Professor Lieberkühn was the son of the discoverer of Lieberkühn's glands. The word should, of course, have been descendant instead of son.

STATISTICAL RECORDS OF INTUBATION, WITH REPORT OF EIGHT HUNDRED AND SIX CASES.

By DILLON BROWN, M.D.,

NEW YORK.

Number.	Date.	Operator.	Sex.	Age.	Duration before intubation of: Laryngeal symptoms.	Duration before intubation of: Pharyngeal diphtheria.	Urine.	Cause of death.	Complications.	Result.

Total number of operators, 65.

Total number of cases, 806, with 221 recoveries, = 27.4 per cent. Male, 225; female, 198.

Average age of fatal cases, 3 years 2 months.

Average age of cases which recovered, 4 years 1⅓ month.

Duration of laryngeal symptoms before intubation in cases of recovery, 2 days 9 hours; in cases of death, 1 day 19 hours.

Urine contained albumen in 117 cases, and no albumen in 31 cases.

In fatal cases, average length of life after intubation, 2 days 8 hours.

In cases of recovery, average time of tube in larynx, 5 days 3½ hours.

Cause of death in 339 cases:

Diphtheritic bronchitis	139
Pneumonia	55
Sepsis	37
Exhaustion	33
Nephritic complications	25
Heart failure	20
Pulmonary œdema	9
Bronchitis	8
Asphyxia, from clogging of tube	9
" " pushing down membrane	2
" " swelling over head of tube	1
" " neglect to notify operator after coughing out tube.	4
Tuberculosis	2
Congestion of lungs	1
Scarlatina	1

A New Pharmacopœia in Austria.—The Austrian government has appointed a committee to revise the pharmacopœia of that country, in order to bring it up to the level of the recent advances in science. The last (sixth) edition of the work was published in 1869.

LARYNGEAL CRAMP OF MUSICIANS AND SPEAKERS.[1]

By THEODORE H. KELLOGG, M.D.,

NEW YORK CITY.

The motor disturbances to which attention is invited in this paper have, it is believed, received no formal description in treatises on laryngology, or in special works on diseases of the nervous system.

They may be defined as professional neuroses of motility, and they are to be classified in that large group of nervous diseases of which writer's cramp constitutes the most familiar type. Inco-ordinate and excessive action rather than loss of motion prevails in them, and hence Ross, not inappropriately, uses the expression "professional hyperkineses" as a collective designation for all forms of professional cramp, and in accordance with this nomenclature the term laryngeal professional hyperkineses has been chosen.

The etiology of these laryngeal hyperkineses is as evident as their pathology is obscure. Clinical observation has established, beyond all doubt, that excessive functional activity is a cause of various forms of motor disease in groups of muscles of the extremities, and in all parts of the body capable of nicely co-ordinated voluntary movements. The motor troubles of writers, musicians, telegraphers, and of a host of manual occupations confirm this fact as regards the hands and arms, and the observation is renewed for the feet and legs in turners, ballet-dancers, sewing-machine workers, and in many other trades. It would be a contradiction of physiological analogy and of etiological law if a similar sequence of disease were not to result from a like cause in the laryngeal muscles, which are capable of such complex associated movements.

The existence of the laryngeal professional hyperkineses might then be reasonably predicated on *a priori* grounds, but fortunately there are observed facts which form a basis for these disorders, and they will now be described. The symptoms and cases naturally fall under two main groups, which may be technically termed hyperkinetic and hypokinetic.

The hyperkinetic group is characterized by spasmodic and inco-ordinate action of the muscles of the larynx, or of muscles immediately associated in phonation or in similar acts. To this group belongs the first case of laryngeal professional hyperkinesis which came under the writer's notice. The observation was made some years ago in a professional flutist—a German, about fifty years of age, of large frame and strong muscular development, and in the enjoyment of apparent good health. Flute-playing in this instance was attended by spasmodic action of the adductors of the glottis and of the tensors of the vocal cords, which were thrown into sympathetic vibration and produced a low-pitched and continuous sound, which was all the more annoying as it could not be prevented by any effort of will.

The only cause known for this affection was the too constant use of the instrument. The patient had made a common-sense diagnosis of his trouble, which he called cramp in his throat, and in speaking of its cause he said: "Das kommt vom zu viel blasen," and thus in a word he gave its true etiology. Gerhardt has reported a similar observation in a man who had already suffered from cramp of the arm, and the analogy between the two affections was thus very direct. In these instances certain sets of laryngeal muscles are called into gentle and concerted action, for there is naturally, the writer finds in his own use of the flute (and no doubt it is true for other flute-players), a slight contraction of the crico-thyroids and of the adductors of the glottis. But when flute-playing was carried to great excess in the above cases these muscles became hyperkinetic, and the constant spasms were such as to interfere with the patients' occupation.

[1] Read at a meeting of the New York Neurological Society on June 7, 1887.

It is well known that in writers the arm as well as the hand may become affected, and it is natuaral to suppose that in players on wind-instruments neighboring muscles of the laryngeal group would become secondarily involved, and it is probable that in them labial, lingual, and laryngeal hyperkinesis may exist synchronously.

Strümpell has already put on record a case of clonic lingual spasm in a clarionet-player, who was thus incapacitated for his occupation. Adequate inquiry would probably reveal many similar facts, and the writer has already had verbal accounts of like instances.

In this first hyperkinetic group should be classed also those cases called choked voice, which are, in reality, instances of expiratory adductor spasm from continued vocal strain ; and cases of painful laryngeal contractions briefly alluded to by Sée, of Paris; and, in fact, all persistent spasmodic symptoms of the singing or speaking voice due to its immoderate employment.

Instances from a like cause, in which the voice habitually breaks from a chest to a falsetto tone, may perhaps belong to this category also, though the supposition of the spasmodic contraction of the vocal cords and of their vibration between nodal points is not fully satisfactory, for it is well known that in unilateral paralysis of the adductors, with vibration of the mere edge of the inefficient vocal cord, there is still falsetto phonation.

In this group, too, are to be included certain allied hyperkinetic conditions which are very rare and interesting. In these instances the rima respiratoria closes during expiration, and, through involuntary action of the tensors of the inferior thyro-arytenoid ligaments, there are produced audible sounds, which receive accidental modification by the position in which the buccal, nasal, and pharyngeal cavities chance to be.

One such instance of expiratory tension of the chordæ vocales and of involuntary phonation has come within the writer's observation. A further symptom of interest in the laryngeal hyperkineses is that ordinarily the adductor spasm is excited only during forced expiratory efforts, and not during inspiration, even though it be voluntarily prolonged. To such an extent is this true that the patient may resort to the expedient of vocalization of the in-going current of air, and thus learn to speak solely with an inspiratory voice. It is probable that in time this inspiratory speech would become also spasmodic, though the only case known to the writer of spasmodic phonation during inspiration was in a stutterer whom he once treated, with only partial success, for some months.

It is well known that paralysis of certain laryngeal muscles may give rise to spasm of others, and when the laryngeal hyperkineses have been more thoroughly studied, it will likely become necessary to establish a mixed group in which paralysis and tonic or clonic spasm will be found to coexist.

With this forethought as to future classification, the second or hypokinetic group of these disorders is mentioned. It is characterized by diminution or loss of power in the laryngeal muscles as the result of continued overuse.

In this connection belongs an observation made by the writer, of a man in fair health, who, during a series of many months, and for several hours daily, read foreign languages aloud. This vocal action was forcible, and sustained with unusual voluntary effort. The final result was paretic loss of voice, with painful sense of fatigue. The laryngoscopic appearances were normal, and there were neither local, catarrhal, nor general constitutional conditions to account for the symptoms. Voluntary reaction of the vocal muscles was simply lost through overstrain, as in the paralytic forms of professional cramp.

To this group belong some of those cases of loss of voice among professional singers and arduous aspirants for the operatic stage.

Teachers of vocal music speak of these cases as due to bad methods of voice-training, and some of them are attended by inflammatory conditions, but a few cases free from all such complications can only be regarded as instances of hypokinesis of overtaxed laryngeal muscles. The paresis may simply reveal itself through inability to evenly sustain tones which may become clearly forced, tremulous, flat, or unmusical, or there may be loss only of a part of the range of the voice, as of the highest soprano or lowest bass notes. The defect of innervation in these instances presumably exists in the lateral crico-arytenoid, arytenoid, and thyro-arytenoid muscles.

In the description of symptoms only expiratory forms of spasm have as yet been noticed, but it is likely that some inspiratory spasms and certain cases of aphonia spastica are to be numbered among the disorders in question, and that the extrinsic as well as the intrinsic muscles of the larynx are sometimes involved in these forms of hyperkinesis.

The main symptoms, then, may be briefly summed up as inco-ordination, paresis, tremor or spasm of laryngeal muscles, displayed especially in expiration and during phonatory efforts.

The pathology of all the professional neuroses of motility is, to say the least, hypothetical. The theories of the myopathic or peripheral neuropathic origin of these diseases do not adequately explain all the clinical facts. The influence of heredity is not to be overlooked in these cases, which occasionally present a distinct "diathesis spasmodica" from earliest childhood. Of course, this instability of nerve-centres may be acquired as well as inherited.

The most plausible theory is that the laryngeal hyperkineses are of central origin—that the prime points of pathological irritability are, first, in cortical centres and, secondly, in the medulla oblongata itself.

The fact that the movements which become disordered are such as are voluntarily co-ordinated, and that they are uniformly initiated by cortical impulses, tends to confirm this view. A purely cortical phenomenon, too, is the painful consciousness of fatigue excited by the simple unexecuted idea of the customary movements.

The diagnosis of the professional laryngeal hyperkineses is to be arrived at by a process of exclusion of certain well-known pathological conditions. Thus there are to be excluded all forms of pressure on the pneumogastric nerves by enlarged glands and various tumors, and on the recurrent laryngeal nerves by thoracic aneurisms ; also, diphtheritic, rheumatic, syphilitic, and other diathetic or toxic states, attended or followed by motor disorders of the larynx.

It is also necessary to eliminate the early laryngeal crises of locomotor ataxia, the aphonia of hysteria, certain reflex spastic states, cases of balbuties spasmodica, and the phonetic inco-ordination of general paresis. In regard to the latter disease, it is to be remarked that professional singers who become cases of general paresis may present laryngeal hyperkinesis as the initial phenomenon.

A noted negro minstrel who died of general paresis under the writer's care had inco-ordination and spasm of laryngeal muscles months before the appearance of any other symptom, either psychical or somatic.

The differential diagnosis is not necessarily more difficult than in other cases of professional cramp which often have superficial resemblances to various motor disorders.

As the larynx, however, is less accessible to observation than the hand or other parts concerned in the professional neuroses of motility, the finer diagnosis of the muscles specially affected in any given case becomes admittedly somewhat difficult. In view of the great advances in modern laryngology, it is believed that it will soon be possible, in cases of speaker's cramp, as in those of writer's cramp, to decide with precision as to the muscles directly involved in every instance.

The prognosis in the laryngeal, as in other kinds of

professional hyperkineses, is bad. The disease is usually of gradual development, and by the time that it is fully pronounced and recognized, it has assumed a chronic character.

In most singers and speakers attacked there is to be expected more or less permanent disability, and the exact prognosis will depend somewhat on the age and constitution of the patient, on the duration of the malady, and on the willingness of the sufferer to persevere in the treatment prescribed.

The treatment of the laryngeal hyperkineses has at least one uniform indication, and that is, complete rest of the muscles affected. All forced expiratory acts like coughing, laughing, and crying should, as far as possible, be avoided, and, above all things, voluntary use of the laryngeal muscles is to be forbidden.

Even the silent reading of musical scores common among singers provokes latent motor impulses, and is harmful.

In the case arising from the reading aloud of foreign languages above mentioned, even mental rehearsal of a few pages without vocalization excited a painful sense of fatigue referable to the larynx

After attention to this first indication for functional repose, the observance of hygienic rules, change of climate and habits of life, hydrotherapy and topical treatment are in order.

Of local measures, electricity and laryngeal massage are perhaps the most effectual.

In fortunate cases the return to the full professional use of the laryngeal muscles should be gradual.

In conclusion, let it be said that this paper is simply a small contribution to the literature of rare neuropathic affections which would seem to have almost escaped recognition. If it serve to excite an interest in their more complete study, its object will have been accomplished.

Progress of Medical Science.

Intra-uterine Death.—Dr. Priestley's Lumleian Lectures on this subject will form an important addition to obstetrical literature. Among the more general causes, some appear referable to the father, for the procreating power is distinct from the developing power, so that, as it appears, a man may beget a fœtus which cannot develop to the end of the normal term of gestation. In the case of the mother, anæmia, starvation, and overfeeding, are active agents in killing the fœtus. Dr. Priestley discusses some important questions respecting the effects of high temperature, the immediate cause of death of the fœtus when the mother is stricken with any complaint where the temperature rises considerably. Runge's experiments show that the temperature in the fœtus is higher than in the mother, and rises proportionately higher when her temperature rises. The fœtus may die solely from high temperature in cases where the mother recovers. Overcharging of the fœtal capillaries occurs in the fœtus, and it is expelled dead by contraction of the uterus, stimulated by the carbonized blood in its sinuses. In puerperal eclampsia the fœtus is killed either by a rise of temperature, or by uterine contractions which cause imperfect aëration of blood, or by uræmic vitiation of blood. Suckling and mental emotion are given as undoubted reflex causes of intra-uterine death. The child is frequently killed by disease of the fœtal appendages, generally due to previous inflammation of the unimpregnated uterine mucous membrane. These diseases are chronic diffuse endometritis, polypoid endometritis, and catarrhal endometritis, the hydrorrhœa of pregnant women. Dr. Priestley dwells at great length on cystic disease of the chorion. It is probably the cause, not the effect, of the death of the fœtus. The embryo either disappears in the cystic mass, or is found shrivelled and wrapped in its amnion, or even without an amnion, in the midst of the "mole." Hydramnios is a cause of fœtal death; this affection is associated with twin gestation, monstrosities, syphilis, and female children. It is rare in first pregnancies. Placental disease plays an important part in causing fœtal death. Dr. Priestley, in accordance with other living authorities, agrees that there must be several distinct diseases of the placenta. The different stages of one disease are liable to be taken for distinct affections. Apoplexy and true inflammation of the placenta, or placentitis, are noted by the lecturer, who then proceeds to speak of a remarkable affection known as placental phthisis. It is not tubercular, no specific bacilli can be found, nor is it essentially a fatty degeneration. A deposit, probably a low type of exudation, is thrown out among the villi. This deposit breaks down and cavities form, which fill with blood. The placenta is thus rendered totally unfit for its functions, and as the dead child is sometimes expelled plump, and otherwise in good condition, this placental disease must run a rapid course. True fatty degeneration of the placenta, described by Drs. Barnes and Kilian, and myxoma fibrosum, a fibroid hypertrophy of the villi sometimes forming distinct tumors in the placental structure, are active causes of fœtal death. It appears that we are not yet able to say with precision that any one distinct lesion of the placenta belongs alone to syphilis. Fränkel describes a "disfiguring granulation cell-disease," the placental affection which appears to be the most frequently associated with syphilis. He further notes that the evidences of placental syphilis vary according as to whether the syphilitic virus is derived from the mother or the father. The treatment of patients subject to bring forth dead fœtuses prematurely cannot be said to be satisfactory. Antisyphilitic drugs are no sure protection against intra-uterine death, even if they do not of themselves kill the fœtus, while curing or producing no effect on the mother, as has been suspected on reasonable grounds. Even rest may, in some cases, be an inferior therapeutic agent to certain forms of exercise. The most satisfactory cases are those where fœtal death has been due to anæmia or debility. Aix-les-Bains has been recommended in these cases. Dr. Priestley believes that the baths of Schwalbach have tonic properties for anæmic patients, while a visit to Kissingen is appropriate for those in whom the digestive and portal systems are at fault.—*The British Medical Journal.*

Aspiration of the Stomach in Drunkenness.—In the *Dublin Journal of Medical Science*, Mr. George Foy relates the following case: One night in November, 1884, he was called to a man reported to be dying. He had taken a large quantity of whiskey and claret, and for two hours his drunken companions had been trying to rouse him, but had totally failed. When seen he was quite insensible; extremities cold, face livid, pupils widely dilated, respiration and pulse almost imperceptible. Treatment was commenced by opening the median-basilic vein of the left arm, when, by rubbing the forearm briskly, the blood gradually flowed until sixteen ounces were drawn off. In the meantime the fine trocar of an aspirator was pushed through the abdominal wall in an upward, backward, and outward direction, just at the sternal end of the eighth rib. The cannula was attached by the ordinary method to an exhaust bottle, and on turning the cock a stream of claret-colored fluid flowed into the bottle. Very soon the heart commenced to beat; the pulse was readily felt at the wrist, respiration recommenced. The cannula was then withdrawn, and a stomach-pump was used to wash out the stomach. Very soon the man was able to speak, and soon recovered. The author saw no good in giving apomorphia in this case, as it has no emetic action when sensibility is quite deadened, while the respiration was too feeble to allow a stomach-tube to be introduced; so that there seemed no chance for the patient unless aspiration was attempted.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, July 23, 1887.

THE ANTI-TOXIC FUNCTION OF THE LIVER.

PERHAPS one reason why there is now so little rational treatment or intelligent recognition of the functional disorders of the liver is the minor importance assigned to it in physiological text-books. In none of the standard works does one find a definite and complete description of the hepatic functions. These one may discover, by studious investigation, to be the secretion of bile, the manufacture of glycogen and discharge of liver-sugar, the production of chemical changes in albumin and fat, modifications of hæmatosis, the detention and neutralization of alkaloids, while incidentally the liver produces a large amount of heat. The main work of the liver is in its powerful influence upon the materials taken into the body for nutrition—its metabolic function.

Among the minor but yet extremely important duties of the liver is its anti-toxic action. M. Héger, in 1873, Schiff, in 1877, and several later experimenters have shown that certain poisons injected into a mesenteric vein were far less potent than when given hypodermically. According to M. Roger (Paris, 1877), such alkaloids as strychnia, quinine, atropine, hyoscyamine, and morphine, are about one-half as poisonous when injected into the portal vein as when given subcutaneously. De Jacques found that the nicotine carried to the liver was precipitated there and was not excreted by the bile, while strychnia and quinine were found in the bile. Further experiment showed that nicotine gets into the general circulation mainly by the lymphatics.

The anti-toxic action of the liver was shown by De Jacques to be due to the formation in the liver of an insoluble combination of the alkaloid with albumin.

The protective power of the liver, however, exercises itself in other ways than on extraneous poisons. There are, it is believed, poisons constantly being formed in the digestive tract. Even peptone in doses of three or four ounces introduced into a peripheral vein is poisonous, while it would require nearly three times as much to produce toxic effects if it were introduced into the liver. The blood-albumin in the portal vein and its tributaries seems to possess some poisonous power which is not present in the blood-albumin of the general systemic circulation. The phenol produced by intestinal decomposition undergoes a change in the liver into the less poisonous substance phenyl-sulphate (Kochs, Roger).

The liver barely acts upon alcohol, however, and does not modify the toxicity of acetone.

In the metabolic changes by which proteids are reduced to urea occur, probably, several stages, in which products are developed that are more poisonous than urea. Thus Bouchard claims to have shown that nitrogen is four times more poisonous as carbonate of ammonia than as urea. While this may be considered somewhat doubtful, it is no doubt true that in a general way the liver constantly reduces the primary products of proteid metabolism into less poisonous and more easily excretable substances.

That the liver, to some extent, destroys ptomaines carried to it in the blood is also an accepted fact.

How does the liver exercise this protective function? De Jacques has shown, by some very precise experiments, that alkaloids are combined in the liver with a proteid. M. G. H. Roger (*Gazette des Hôpitaux*, 1887, p. 527) has brought forward some striking facts to prove that it is the glycogen of the liver which gives to it its anti-toxic power. In starved animals or in those in which, by dieting, the glycogen had been reduced to a minimum, poisons acted very quickly. On the other hand, by increasing the amount of hepatic glycogen, poisons injected were much less innocuous. He also found that toxic alkaloids heated in a closed vessel with glycogen had their toxicity greatly lessened.

The practical deduction from M. Roger's experiments is that in diseases attended with auto-intoxication, such as the infectious fevers, for example, it is of the greatest importance to keep at its highest point the glycogenic activity of the liver. This is to be done by a suitable diet, avoiding beef-tea and soups, but giving plenty of milk. In addition, partial intestinal antisepsis is to be obtained by the use of naphthaline. The use of substances containing large amounts of the salts of potassium is deprecated, since these salts are shown to be quite poisonous.

A NEW OPERATIVE PROCEDURE IN THE TREATMENT OF HERNIA.

THE results of herniotomy, as at present practised, are far from satisfactory, for, although the operation is undoubtedly efficacious in saving many lives that would otherwise be sacrificed, the death-rate following its performance is not inconsiderable. For this reason a new method, advanced by Dr. A. C. Bernays, and described in the St. Louis *Medical and Surgical Journal* for May, 1887, would seem to be worthy of the attention of surgeons.

The operation, which consists simply in the subcutaneous tenotomy of Poupart's ligament, is described by Dr. Bernays as follows: A small incision, one-eighth of an inch in length, is made through the skin only, in a vertical direction, exactly in the inguinal fold. Next, a probe-pointed knife is pushed through the subcutaneous fatty tissues under Poupart's ligament, which is found tense, and, by pressing the ligament against the edge of the knife from without with the left hand while the right hand holds the tenotome, the ligament is cut. The knife is withdrawn as soon as the resisting ligament is cut. If, after the probe-pointed knife is introduced, Poupart's ligament is found relaxed, it should be immediately withdrawn; for, in all probability, the case is then one in which the strangulation is caused by the sac

itself, and its cause is not to be sought for in the inguinal or femoral canal. After the ligament is cut, the hernia will, it is stated, almost immediately slip back, if the patient is not too deeply anæsthetized, or it can be returned to the abdominal cavity with the greatest ease by manipulation.

The after-treatment must consist of perfect rest in a recumbent position, in order that union of the cut ends of the ligament may take place. Judging from the experience of tenotomy upon other tendons, one week ought to be sufficient in most cases to achieve an organization of the lymph which will be poured out between the cut ends.

The author recommends that the incision be made about an inch from the hernial protrusion in the direction of the spine of the ilium, though he thinks it quite possible that an incision of the lateral half, or nearer the spine of the ilium, will perhaps answer as good a purpose as a division of the median portion of Poupart's ligament nearer the seat of strangulation. The effect of dividing the ligament is a complete relaxation of the external and internal ring and all intermediate parts of the canal, as well as of Gimbernat's ligament and the femoral ring.

The operation is certainly simple and easy of performance, and would seem to be devoid of danger. In the two cases in which Dr. Bernays had employed it, at the time his article was written, the results, both immediate and remote, were entirely satisfactory.

THE REPORT OF THE BRITISH HYDROPHOBIA COMMISSION.

By far the most important medical event of the present year is the publication of the report of the British Commission on Hydrophobia. Taken in connection with the report of Dr. Ullmann before the Royal Society of Physicians of Vienna, we are now asked to accept as a fact that Pasteur has devised a method by which animals can be given immunity against rabies. Furthermore, it is also claimed that, by means of serial inoculations, animals who have been bitten by rabid dogs can be kept from developing the disease. The confirmation by the Commission of these two claims of Pasteur implies that the earlier investigations were also substantiated, by which he discovered that the virus was contained in the spinal cord, that it could be transmitted by inoculation, that it was intensified by being transmitted through rabbits, and exhibited itself in the furious, the paralytic, and the mixed forms of rabies.

The great practical question now comes, as to whether it is shown that the serial inoculations of dried cords prevent the development of hydrophobia in men who have been bitten by mad animals. Although the evidence does not amount to exact demonstration, the Commission present it in such a way as to give a moral support to the correctness of Pasteur's claims. The Report states that Professor Burdon Sanderson, Dr. Lauder Brunton, and Mr. Victor Horsley went to Paris in May, 1886, and personally investigated the history of 90 patients residing in Paris, Lyons, and St. Etienne, whose names appear consecutively on M. Pasteur's list. Full particulars of all these patients are given in an appendix. In 31 instances there was no reliable evidence that the dog was rabid, in others the bites were inflicted through the clothes; but in 24 the patients had been bitten on naked parts by undoubtedly rabid dogs, and the wounds were not cauterized or treated in any way likely to have prevented the action of the virus. None of these 90 persons have died of hydrophobia. The Committee estimates that 8 would have died if the inoculations had not been practised. This (says the *British Medical Journal*) is the most precise evidence obtained by the Committee, but it would be difficult to over-estimate its value, and it is well worthy the great time and pains expended in obtaining it. No previous observers or critics have contributed any evidence of the kind, and it must be held fully to confirm the claims advanced by M. Pasteur. The other statistics given are of a kind with which we are already familiar; taking the whole series of cases inoculated from October, 1885, to December, 1886, and using the lowest mortality ever estimated for untreated cases (five per cent.), the Committee is of opinion that, "making fair allowance for uncertainties, and for questions that cannot now be settled, we believe it sure that, excluding the deaths after bites by rabid wolves, the proportion of deaths in the 2,634 persons bitten by other animals was between 1 and 1.2 per cent., a proportion far lower than the lowest ever estimated among those not submitted to M. Pasteur's treatment, and showing, even on this lowest estimate, the saving of not less than 100 lives."

It is also stated that it has been proved, either by inoculation experiments with their spinal cords, or by the occurrence of rabies in animals also bitten, that in the cases of 233 persons bitten the dogs were indubitably rabid, yet only 4 persons died; whereas the Committee estimates that at least 40 would have died if the inoculations had not been performed. Even the cases of the 48 patients bitten by rabid wolves, of which so much has been made by M. Pasteur's opponents, are made to tell in his favor, for the Committee estimates that, if untreated, nearly 30 would have died, whereas only 9 actually succumbed. Further, it is stated that, during the first three months of this year, M. Pasteur had inoculated 509 persons bitten by animals proved to have been rabid, either by inoculation or by the deaths of animals bitten, or so certified by veterinary surgeons. Of this number only 2 have died, and one of these had been bitten by a wolf a month before the inoculations were commenced, and died after three days' treatment.

The practical conclusion at which the Committee has arrived is, that until police regulations of the most stringent kind can be enforced with complete success, there will always be a considerable number of persons who will require treatment by the method of M. Pasteur. During the ten years ending 1885, the annual average of deaths from hydrophobia was 43, and this probably represents a total number of over 800 persons bitten by rabid dogs; it is not possible to say which, among this whole number, are not in danger of hydrophobia. Police regulations applied over the whole of Great Britain would very materially diminish this number, but the Committee is of opinion that, to be effective, the regulations must require (1) the destruction of all wandering, ownerless dogs; (2) discouragement of the keeping of useless dogs by taxation or other means; (3) prohibiting importation

of dogs from countries where rabies is prevalent, or the imposition of quarantine; (4) compulsory use of muzzles in districts where rabies is prevalent.

In this city the average annual death-rate from hydrophobia for the twenty years from 1854 to 1874 was 2.3, and the average number of persons bitten would be 46. For the whole country, the average annual death-rate should be not far from 100 persons annually, with 2,000 bitten. Inoculations would save 80 lives annually, if we accept the conclusions of the Commission. It is for the public to say whether it is worth while to undertake such a work.

THE INFLICTION OF THE DEATH-PENALTY.

THE July number of the *Forum* contains a very readable article by Mr. Park Benjamin, with the above caption. The particular point made is concerning the manner in which the death-penalty should be inflicted—in those cases where the law has decreed it. Hanging he condemns as barbarous, and he denounces the manner in which executions are carried on. He claims that the large number of persons allowed to be present tends to martyrize the unfortunate man. Even the part allotted to medical men on such occasions, of listening to the heart-beats after the drop has occurred, he cannot reconcile himself to. He then discusses the various methods which have from time to time been suggested as a substitute for hanging.

"Any proceeding which the subject can physically oppose, or of which he can ward off the deadly effect for a reasonable period of time, is unsuitable. This sets aside suffocation by carbonic-acid gas, drowning, and the use of deadly anæsthetics, and, even more certainly, all forms of poison. The hypodermic injection of poison, which lately has found many advocates, fails to meet the requirements that death must be caused instantly—just as rapidly to the strongest as to the weakest individual."

There is something sublime in the picture which historians have drawn for us of the manner in which Socrates calmly awaited the approach of death after having taken the fatal hemlock. Firm in the faith of his convictions, his last words were those of inspiration and encouragement to his fellows. His uninspired words form perhaps the nearest approach to inspiration of any in profane writings. With the modern sufferer of the death-penalty we should not expect such affecting surroundings, and his great desire would probably be to "die game."

Mr. Benjamin sensibly argues that "any proceeding which involves the application of medical or surgical skill to insure its efficiency must likewise be ruled out. The medical faculty, presumably, will not assume the rôle of executioners. A physician may be called upon, as now, to distinguish apparent death." This will, of course, at once decide against pithing the medulla. Public sentiment will declare against any mutilating methods, and even shooting, which is, perhaps, the most speedy method of all thus far alluded to, is open to many objections.

Having mentioned all these methods to decry against them, the writer brings forward electricity as the method which is the most speedy and humane, and destined to eventually supersede all others. Sensation, as a physiological process, requires, he says, one-tenth of a second. Any method, therefore, which requires less than this time for its performance is absolutely painless. Tyndall, in one of his experiments, accidentally received a very large charge of electricity from some apparatus, and declared that there ensued in his system an appreciable interval in which all the powers of life seemed to be held in abeyance, and in which he experienced no pain. The electrodes might be placed one under the feet and the other at the base of the brain. The pressing of a button would close the circuit, or the closure might be made by some clock-work apparatus, and thus the execution would take place without the direct intervention of a human hand.

One argument advanced in favor of electricity may seem to some a rather curious one. It is the horror inborn in man of instantaneous death. The litany, we are reminded, contains a distinct supplication that we may be delivered from "sudden death." It is argued that this inherent fear would surround the death-penalty with more of terror and abhorrence than now exists, and that certain classes of evil-doers would be more powerfully deterred from crime than they are under the existing state of affairs. In the use of electricity, the fatal result would be positively assured. Judicial executions are often shocking blunders. The experiments of D'Arsonval have shown that while, after a shock of under five hundred volts, life can generally be resuscitated by artificial respiration, a stronger electro-motive force is absolutely fatal.

From some of the minor conclusions of the article under consideration we might dissent. With the major ones we are disposed to agree. Before any method of inflicting the death-penalty may become the ideal one, a vigorous reformation in attendant circumstances is necessary. It is a judicial procedure, and should be surrounded with the law's stern majesty.

THE QUESTION OF PLAGIARISM.—We are quite willing to admit the injustice of calling it plagiarism, for the *Provincial Medical Journal* to publish without acknowledgment an article which first appeared in the RECORD, but which was sent directly to the former journal by the author. We have a right to be suspicious, however, of the journal in question. On February 16, 1884, we published an editorial on "Bromoform." This appeared copied exactly, without acknowledgment, in the editorial columns of the *Provincial Medical Journal* (then the *Midland Medical Miscellany*) for April 1, 1884. On June 2, 1884, we published an editorial entitled "The Mobility of the Brain." This was also copied *verbatim* in the editorial columns of the same journal for June 2, 1884. Whether other unacknowledged copying was done we cannot at this moment say.

News of the Week.

The Status of Medical Practitioners in Minnesota.—There are in Minnesota 1501 licensed physicians, and 10 un-licensed. Of the licensed, 1268 are regulars.

A Strong Inducement.—An Australian doctor advertises to pay one-half the funeral expenses in cases in which he is not successful.

Canada and Her Foundlings.—The medical health officer of Montreal has made an investigation regarding the care of the city's foundlings, and states, according to the *True Witness*, that out of over 700 in the care of the Grey Nuns, 678 died during one year.

Laryngology in Berlin.—A new clinical institute is to be opened in Berlin next week. It is to be devoted to the study of diseases of the nose and throat. Professor B. Fraenkel will lecture on laryngoscopy and rhinoscopy, and on the local medication of the upper air-passages.

The Medical Department of the University of Vermont held its thirty-fourth annual commencement at Burlington, on July 15th. Fifty-three candidates received degrees. The annual address was delivered by Hon. James W. Patterson, of Hanover, N. H.

Dr. Ariel Ballona, of Woonsocket, R. I., died on July 15th, at the age of eighty-two years. He was for fifty years a medical practitioner in Woonsocket. For many years he was prominent in the politics of the State.

Properly Equipped.—All the conductors on the Maine Central Railroad have been provided by the management of the road, with cases containing all the remedies to be used in cases of accident.

A Branch of the British Medical Association has been organized in Halifax, N. S. This is the first branch of the association in North America.

as a fact that Pasteur has devised a method by which animals can be given immunity against rabies. Furthermore, it is also claimed that, by means of serial inoculations, animals who have been bitten by rabid dogs can be kept from developing the disease. The confirmation by the Commission of these two claims of Pasteur implies that the earlier investigations were also substantiated, by which he discovered that the virus was contained in the spinal cord, that it could be transmitted by inoculation, that it was intensified by being transmitted

, contains only 1,920 [illegible] 1,400 physicians, so-called, in our city, are not recognized as such by the editor of the Register. These include homœopaths, eclectics, etc.

The Gross Medical College is the name of the newly organized Medical Department of the Rocky Mountain University, situated at Denver, Col. As Denver has a population of eighty thousand, and only one medical college, the need of a second is most apparent. The State of Colorado, also, having a population of over two hundred thousand, and only two medical colleges, plainly needs a third.

Sanitary Congress at Lima.—The Peruvian Government has invited the Republics of Central and South America to co-operate in the formation of a sanitary congress to be held at Lima, November 1st.

Civil Service Reform and Illiteracy at Buffalo.—According to the Buffalo *Medical and Surgical Journal*, the recent stir made by the County Society over the matter of preliminary education was brought about in an unexpected way. An examination was held by the Civil Service Commission for the position of District Health Physician. The medical applicants made such an extraordinarily poor showing in grammar, literature, etc., as to surprise the examiners and lead to the discussions which ended in action by the County Society.

The Treatment of Hysteric Cephalalgia by Compression.—At a recent meeting of the Paris Biological Society, M. Féré communicated a note on the above subject. Manual compression in such cases being too tiresome for the operator on account of the length of time required—half an hour or more—the author had recourse to a mechanical contrivance. The instrument best suited to the purpose consists of cushioned sacks, filled with shot, which may be formed into any conceivable shape. In this way a helmet may be made, producing any required pressure. In four cases cited by the author, satisfactory results were obtained by this method of treatment. When the pain, however, as often happens, is in both temples, the difficulties of compression are best overcome by means of a compressor provided with a spring, as constructed by M. Aubry.—*Sacramento Medical Times.*

The Old Building of the New York College of Physicians and Surgeons is to be occupied as a Business College.

Obituary.

JOSEPH C. HUTCHISON, M.D., LL.D.,

BROOKLYN, N. Y.

Dr. Joseph C. Hutchison, of Brooklyn, died of pneumonia, July 17th. He had been ill for over a month. Dr. Hutchison was born in Old Franklin, Mo., sixty years ago. He graduated in medicine at the University of Pennsylvania in 1848. After practising four years in Missouri he settled in Brooklyn and remained there, building up one of the largest practices in the city. He was a member of the Kings County Medical Society, and in 1864 was its president. He was also connected in various official capacities with the New York Medical Society, the New York Pathological Society, was a Fellow of the New York Academy of Medicine, and an honorary member of several Connecticut and New Jersey medical societies.

Dr. Hutchison gained his laurels in surgery, and since 1854 he was connected, at different times, with every hospital in Brooklyn. Previous to that time he had devoted himself to a study of cholera, and was physician in charge of the Cholera Hospital. He founded the Brooklyn Orthopedic Infirmary, and was its chief surgeon for many years. In 1860 he became Professor of Operative and Chemical Surgery in the Long Island College Hospital, and continued in that position for seven years. For three years, beginning in 1873, he served as Health Commissioner of Brooklyn. Several important works on surgery resulted from Dr. Hutchison's long study of the subject.

Dr. Hutchison was a delegate to the International Medical Congress, held in Philadelphia in 1867, and to that in London in 1881. In 1880 he received the degree of LL.D. from the University of Missouri.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 27, 1887.

T. Mitchell Prudden, President, in the Chair.

Dr. Frederick Peterson (Poughkeepsie) presented portions of lungs from a case of

ANTHRACOSIS PULMONUM.

G. R——, sixty-seven years of age, and a worker in the cleaning-room of a stove foundry, fell dead in the street. Dr. Peterson was sent by the coroner to make a post-mortem examination, which took place five hours after death. The body was well formed and well nourished. *Rigor mortis* absent. The pupils were dilated. There was nothing abnormal about the brain.

Thorax: On opening this cavity both lungs were found bound to the chest-wall by old and strong adhesions. They were extraordinarily black over the whole surface, and strikingly hard and lobulated (very much like a cirrhotic liver, except that the nodules were larger). There were numerous patches of emphysema, the dilated and confluent air-vesicles being in places the size of peas. There was œdema to a great degree in both lungs. In the left pleural sac was about a litre of clear serum. The whole upper lobe of the right lung was one extremely hard tumor, like a fibroma, and perfectly black on cutting through it. In this tumor was a small abscess the size of a hazel-nut. When the hands were brought into contact with a freshly cut lung-surface, they became discolored and blackened, as if one were handling bone-black with wet fingers. The bronchi, bronchial tubes, and trachea had clean, white mucosæ. The mediastinal glands were greatly hypertrophied, wholly black with carbon, and very hard. The pericardium contained sixty cubic centimetres of clear serum. The endocardium was exceedingly fatty, somewhat hypertrophied, and dilated. This fatty metamorphosis was, of course, due to the condition of the lungs. The mitral, pulmonary, and aortic valves were somewhat thickened, and at the bases of the pulmonary and aortic lunulæ were small calcified patches, but not sufficiently large to produce stenosis of the orifices. There was an advanced general endarteritis deformans.

Abdominal cavity: The *spleen* was a little enlarged, hard, and very adherent to the diaphragm. The *liver* was small, very fatty, and everywhere strongly adherent to the diaphragm. There was chronic *gastric* catarrh. Both kidneys showed signs of senile atrophy. All the other organs were normal.

A certificate of death from fatty degeneration of the heart was made out. The most interesting pathological objects were the lungs, with their enormous quantities of carbonaceous matter, and also in the lymphatic glands in their neighborhood. Undoubtedly this carbon had caused fibrous phthisis, the pleuræ and peritoneum on the diaphragm subsequently becoming involved.

This man had worked in the cleaning-room of the stove works for thirty-one years. During all this period he had at no time manifested physical illness other than a "terrible morning cough," as his wife termed it. The cough he had had always while at this occupation. In this cleaning-room is brushed from the iron castings the charcoal dust which is used in their manufacture. The atmosphere of the room is so dense with carbon that one can scarcely see through it, and it is nearly irrespirable to one unaccustomed to it. There is also a small amount of sand in the air. ALL OF THE LARGE FORCE OF MEN EMPLOYED IN THIS ROOM SUFFERED FROM PULMONARY DIFFICULTIES. The case was interesting because it showed what devastation this occupation could cause in the lungs, and yet how assiduously one could pursue it without apparent shortening of his life. It was probable that this particular man had a fine constitution. But many others had spent a decade or more in the same room without further detriment than the bronchial catarrh and cough.

Dr. Ira Van Gieson presented a

KIDNEY CONTAINING A LARGE CALCULUS.

The main part of the stone was cylindrical, *five* centimetres long and one centimetre in diameter, and was lodged in the sinus of the organ, with two prolongations, each about one centimetre long, entering into calyces. There were indentations of the surface of the kidney corresponding to the position of the branches of the calculus in the calyces.

Dr. Van Gieson also presented specimens illustrating the lesions of

PHOSPHORUS-POISONING,

death occurring on the fourth day.

A middle-aged man, on February 1, 1887, dissolved a box of ordinary phosphorus matches in a glass of water and drank it. He entered Bellevue Hospital twenty-four hours afterward, where he was given tea, which he immediately vomited. He continued to vomit all medicine which was given him and died, February 4th, at noon, with slow respiration and jaundice.

Autopsy, twenty-four hours after death. The *heart* showed grayish-white patches near the ventricles; the valves were normal. Old atheroma in the aorta; small ecchymoses beneath the diaphragmatic pleura. *Lungs* œdematous and congested; *bronchi* trabeculated, and contain muco-pus. *Liver* enlarged, fatty, with slight increase of interstitial connective tissue. *Kidneys*. The capsules were adherent, the cortical markings distinct, the labyrinths grayish-white in color, and looked swollen. *Spleen* slightly enlarged. In the *stomach*, near the upper curvature and near the pylorus, there was an oval patch of erosion of the mucosa about three centimetres long; there were also smaller scattered erosions. In places the mucosa had a dull, grayish-white, thickened appearance. The mucosa of the *duodenum*, for a short distance beyond the pylorus, showed the same appearance, but there were no erosions. The *small intestine* and Peyer's patches showed chronic congestion. In the *trachea* the mucosa was covered with closely aggregated translucent elevations, looking like

MILIARY TUBERCLES.

These ceased at the bifurcation. At the bifurcation of the primary bronchi there were a number of deep pin-point erosions. The *œsophagus*, near pylorus, was covered with a brownish adherent film, and there were several small sharply defined erosions of the mucosa. Several of the cervical lymph-glands were of a deep-red color. The *mesenteric glands* were normal.

Microscopical examination.—In the *heart* fatty degeneration; the *lungs* showed the lesions of heart disease. In the *liver* the cells were swollen and contained fat droplets. The *kidneys* showed the lesions of parenchymatous degeneration. In places in the *stomach* the mucosa was nearly of normal thickness; in other places the thickness was much decreased; in places the principal cells of the follicles were swollen and granular, and completely filled the lumen of the follicle; in other places the principal cells were few in number, and the peptic cells were very numerous. With osmic-acid staining both varieties of cells showed minute fat-droplets. The epithelia of *Brunner's glands* were swollen and granular—as were the cells of the *pancreas* and the mucous glands of the trachea. It was the swelling of the latter cells which caused the prominent elevations of the mucosa. Sections from one of the bronchial glands showed miliary tubercles. The deep-red, cervical lymph-nodes showed a distention of the peri-follicular spaces and the lymph-sinuses of the medulla of the node, with red blood-cells,

and there was a notable decrease in the number of small round cells in these nodes. One of the bronchial glands exhibited the same appearance.

Remarks.—The following were the interesting features of the case: First,

THE VERY SELECT AREA OCCUPIED BY MILIARY TUBERCLES—NAMELY, ONLY ONE BRONCHIAL GLAND.

This showed one of the stages in the development of tuberculosis, and illustrated that constant breathing of tubercle-bacilli might, in some, set up tuberculosis of the bronchial glands. The second point of interest was the peculiar appearance presented by some of the cervical glands, as if a blood-vessel had ruptured into some of the lymph-channels, or the blood had been conducted into these glands and had lodged into the peri-follicular spaces and lymph-sinuses of the medullary portion. Specimens were exhibited under the microscope.

The stomach was interesting on account of the *increased number* of *peptic cells*, probably due to the stimulating effect of the phosphorus, and a conservative effort to supply the place of those that had been destroyed by the poison.

The President remarked that the specimens presented by Dr. Van Gieson showed remarkably well the lesions which had been described, and he regarded them as especially interesting in connection with the question of the absorption of pigment in the lungs, shown to such a remarkable degree in the specimens presented by Dr. Peterson.

LARYNGEAL, TRACHEAL, AND BRONCHIAL DIPHTHERIA—INTUBATION.

Dr. A. Brothers presented specimens from a case of diphtheria with the following history:

F——, aged nineteen months, was seen first on the morning of April 5, 1887. The boy had been suddenly taken sick during the previous night with symptoms of croup. At his first visit the temperature was 103° F. and respiration 35. The cough and breathing were distinctly laryngeal. There was moderate dyspnœa. with dilated nostrils. Dr. F. Huber, who saw the case at this time, expressed it as his opinion that the dyspnœa was in part pulmonary. An examination of the lungs showed dulness over the upper portion of the right lung. By night the difficulty in breathing had become decidedly worse.

THE THROAT SHOWED CONSIDERABLE MUCOUS DISCHARGE, BUT NO FALSE MEMBRANE.

There was marked retraction visible in the supra-clavicular and epigastric regions with each inspiration. The lips were beginning to be cyanotic. In view of the urgency of the symptoms, Dr. Brothers decided to intubate, and succeeded, after several attempts, in introducing the O'Dwyer tube. This was followed by the characteristic cough and immediate abatement of the dyspnœa. On the following day the temperature was 101° F. and breathing 35 per minute. The child had not slept much all night. On the 7th the child was decidedly worse. The temperature was 102½° F. and respiration 50. The dulness over the right lung had increased. On the 8th the temperature was 103½° F. and respiration 60. It was now impossible to nourish the child, on account of the severe paroxysms of cough caused by each attempt to swallow. During the night the child became worse, and died on the morning of the 9th—the fourth day after intubation. The treatment had consisted of bichloride of mercury (one-fourth grain in the twenty-four hours), brandy, antipyretics (antifebrin and antipyrin), and steam inhalations.

Autopsy.—This was made five hours after death, with the assistance of Dr. A. T. Joyce. An incision in the neck only was permitted. The portion of tonsils and pharynx removed presented no false membrane. The larynx with its contained tube was taken out, and showed the latter to be in proper position. The arytenoid cartilages were slightly eroded at those points which had served as support for the shoulder of the tube. The lower end of the tube was not obstructed by membrane. Its cavity contained a gelatinous material, probably a mixture of mucous and membranous débris. The larynx, trachea, and larger and smaller bronchi were lined by false membrane which could be peeled off. The lower lobe of the right lung was completely hepatized, so that a section of it in water at once sank to the bottom. The apex of the left lung was in a similar condition. There were no pleuritic adhesions. The other organs were not examined.

Dr. Brothers made a very careful examination of the smaller bronchi, but could not find evidence that any particles of food, after intubation was practised, entered the lungs. The epiglottis covered the tube, and there was evidence of pulmonary consolidation before the tube was introduced. The case did not speak against intubation, because there was evidence that false membrane was present in the smaller bronchial tubes before the tube was introduced, thus putting it in the class of cases in which the disease is almost always fatal.

Dr. Frank Ferguson presented a

FRESH SET OF SPECIMENS.

They were interesting on account of their freshness and the multiple lesions which they illustrated. They were taken from the body of a man forty-eight years of age, a native of Ireland, and a trunkmaker by occupation. He was admitted into the service of Dr. George P. Wheelock, attending physician to St. Luke's Hospital, on April 26, 1887, to whom he was indebted for the clinical notes and the opportunity to present the material. The patient never had rheumatism. When three years of age he had scarlet fever. His family history was negative. For a long time he used alcohol freely, taking it often before breakfast.

For years previous to his admission into the hospital he had swelling of his feet and lower part of the abdomen, lumbar pain, headache, visual disturbances, and dizziness.

Three weeks before his death his feet, scrotum, and abdomen became greatly swollen, which gradually increased until his death. He suffered greatly from dyspnœa, he became delirious, and died twenty-four hours after admission. He said at the hospital that he had passed no urine for four days, and no fæces for five days.

Autopsy.—There were one hundred and twenty ounces of serum in the peritoneal cavity, and a few ounces in each pleural cavity. There were four ounces of serum in the pericardium. The *heart* was large and soft, and its muscular tissue contained fat. The valves were competent. The *lungs* were congested and œdematons. The *spleen* was four times its normal size, and very soft. The *stomach* was very intensely congested. The mucous membrane was thickened, but its muscular wall was normal. The *kidneys* were firm in consistency, the capsules were not adherent, the surfaces were smooth, and the markings of cortex were quite distinct. There was fat in the straight tubes. The *liver* contained a very great quantity of fibrous tissue and fat. The *pancreas* was fatty and very firm in consistency. It was slightly larger than normal.

The Society then went into executive session.

Stated Meeting, May 11, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

MEASLES FOLLOWED BY PNEUMONIA.

Dr. W. P. Northrup presented specimens removed from the body of a child that died in the New York Foundling Asylum, and for the clinical history of the

case he was indebted to Dr. Meyers, house-physician. The child was brought in on May 3d, sick with measles, and it died of pneumonia on May 11th. There was only slight disturbance of respiration, and no symptoms of croup. What dyspnœa existed was supposed to be due to well-marked double pneumonia.

At the autopsy, which was performed very early, there was found false membrane from the tip of the nose to the terminal portion of the finest bronchi. In the larynx there was abundance of false membrane, and yet

THERE WAS NO EVIDENCE OF CROUP.

This point was interesting in connection with cases of measles which he had seen with croupy cough, and yet no false membrane was found. But, at the anterior commissure of the vocal cords there was found a small ulcer, which showed a slight amount of fibrin in the slough. If that was diphtheria, it was the only spot where it existed. In the measles cases there was marked croupy cough and loss of voice. In this case there was neither loss of voice nor symptoms of croup, and it was not suspected that there was any exudation in the larynx. The false membrane was also abundant in the trachea, and it could be distinctly traced into the lungs as a thick, tough membrane. The lower lobe of the left lung was nearly solid, and that of the right one presented the same appearance, and corresponded to the condition described as collapse. But he inflated the right lung, and the inflation was easily made complete. This had been given as

ONE OF THE CRUDE TESTS FOR ATELECTASIS,

and therefore, according to the test, the condition present should be that of atelectasis, and not of pneumonia. In no case, however, of diphtheria of the trachea and bronchi, where the lungs showed these elevated and depressed areas upon the cut surface, had he failed to find

EVIDENCE OF PARENCHYMATOUS PNEUMONITIS.

That is, in the alveoli were found pus, swollen epithelia, and occasionally fibrin.

This child was sick, from the third until the eleventh day of May, with measles and pneumonia. Within half an hour after death he drew urine from its bladder, and found that it contained albumen. It also contained casts in abundance, and the kidney was found to be the seat of parenchymatous nephritis. The kidneys were exceedingly anæmic—so markedly so that he suspected the pale appearance might be due to the rapid exsanguination caused by making the post-mortem so early. The lungs, also, were anæmic, except where the pneumonia existed. This he had seen before, but had never seen the peculiar pallor of the kidneys.

Dr. Northrup also presented specimens from a case of

GENERAL TUBERCULOSIS WITH HEMORRHAGES IN THE FLOOR OF THE LATERAL VENTRICLES, AND DILATED TUBERCULOUS BILE-DUCTS.

The child was aged two and a half years. No diagnosis was made. The complaint was that, on the day previous, it vomited. It was admitted at ten o'clock, had eleven convulsions, and died the next morning at 8.30 o'clock, never having recovered consciousness.

At the autopsy the cerebral convolutions were found very much flattened, the ventricles dilated and containing from four to six ounces of fluid, and on the floor of the lateral ventricles, beneath the ependyma, were found minute punctate hemorrhages. There were tubercles upon the ependyma and at the base of the brain. There were tubercles in the lungs, without consolidation.

The *liver* was very much enlarged, the bile-ducts were dilated, stained with bile, and had thickened walls surrounded by diffuse tubercular tissue. He had not seen this condition of the bile-ducts in adults, but he believed that it was present in the majority of cases of extensive tuberculosis in children.

Dr. Heineman remarked that the portions of lung involved in pneumonia in *children* were frequently below the level of the cut surface, which was one of the striking differences between the appearance of pneumonia in children and that of adults, where the portions involved were frequently *above* the level of the rest of the surface; that is, above the portions containing air.

Portions of these lungs become collapsed and settle below the level of the surrounding parts containing air, because the bronchi are involved and prevent expansion of these particular groups of acini; so that the collapse is simply an accident, and not of much importance, although it had been made much of. He was unable to see why the test should ever have been brought forward; that if a lung could not be inflated it was pneumonic, whereas a pneumonic lung could be inflated. If a little mucous plug at the terminal part of a fine bronchial tube could give rise to feeble respiration and prevent proper inflation during life, he was unable to see why a slightly increased force could not inflate it after death, as had been done in these lungs presented by Dr. Northrup, by applying a comparatively slight degree of force.

As to the anæmic condition of the kidney, he doubted if the mere fact of emptying the organs of blood by a sudden gush from the divided aorta had anything to do with the gross appearance which required the microscope for its solution.

Dr. Cheesman had seen the same pale appearance of the kidneys of rabbits that had been bled to death rapidly.

The President fancied that a good deal that had heretofore been said concerning the color of organs after death would have to be revised. He would ask Dr. Northrup if he had noticed any of the karyokinetic figures in his search for evidence that the new cells were produced from the epithelia of the alveoli.

Dr. Northrup said that he did not. He would inquire if this condition of the gall-ducts had been noticed in adults.

Dr. Heineman remarked that tubercle of the gall-ducts in adults was not common; perhaps for the same reason that in general tuberculosis, tubercles were usually very abundant in the liver of children, whereas in the adult liver only a few were found.

The Society then adjourned.

Syphilitic Broncho-pneumonia.—Drs. Balzer and Grandhomme have recently made several necropsies of syphilitic still-born infants, and the result of their examinations proves that syphilitic lesions which are caused by microbes, like other inflammation, do not appear to preserve any specific character in their evolutions. With regard to the lungs, syphilitic pneumonia may be classed with broncho-pneumonia, in the same degree as secondary pneumonia in acute infectious diseases, such as measles, or in chronic affections like tuberculosis. Syphilis in the fœtus assumes the different forms of broncho-pneumonia and other lesions according to its violence and the degree of its chronic stage. The authors classify these forms of broncho-pneumonia as follows: 1. Recent or slight broncho-pneumonia, including pulmonary congestion, and lesions which are not apparent on microscopic examination. 2. Broncho-pneumonia or agglomerated nuclei disposed in a vertical band at the posterior portion of the lungs. These forms correspond, with regard to lesions, to subacute forms of broncho-pneumonia of other infectious disease, and insensibly assume the following type: 3. Broncho-pneumonia with white hepatization, without dilatation of the bronchi, corresponding to the hepatization of other forms of broncho-pneumonia. It may lead to fibro-caseous or gummy degeneration. 4. Broncho-pneumonia accompanied by dilatation of the bronchi. In conclusion, it may be said that pulmonary syphilis is identical at different ages.—*American Lancet.*

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 7, 1887.

THE PRESIDENT, C. L. DANA, M.D., IN THE CHAIR.

DR. E. C. SEGUIN presented a case of

ABNORMAL CHOREA, WITH EJACULATORY NOISES.

The patient was a boy, twelve years of age, who for a long period had suffered from violent choreic movements, with ejaculatory noises. The disease had been but little modified by treatment. Several drugs had been used, and hyoscyamin had, within limits, controlled the symptoms. Two to five tablets, each containing $\frac{1}{100}$ of a grain, had been given per day, and the patient had borne this daily dose of $\frac{5}{100}$ of a grain without mydriasis or dryness of the throat. The patient was now under the observation of the Neurological Commission, and had had during the past week two operations upon his eye-muscles. As a theoretical explanation of the patient's condition, he suggested discharges from the motor area of the cortex. If ordinary chorea were assumed to be due to discharges from one or the other side, or from both simultaneously, it was but fair to assume that the laryngeal spasm and the ejaculatory language were also due to an appropriate cortical discharge—the words from an implication of the foot of the left third frontal convolution, the well-known region of Broca, and the laryngeal noise from the implication of the foot of the right third frontal convolution, as four recent autopsies had located the centre for the laryngeal muscles in this region.

DR. GRACE PECKHAM had a case of laryngeal spasm which had persisted during all but the most profound sleep, but which had yielded to hypnotism after resisting all other treatment. The patient was a woman, thirty-three years of age. The spasm involved the laryngeal muscles and the diaphragm, the sound being that of an exaggerated hiccough. Antispasmodics had had no effect. The metals were used, and zinc and copper each controlled the paroxysms for about a month, when their influence ceased. The patient was easily hypnotized, going into a profound sleep. At first the spasms were interrupted for an hour, later for several days, then for a week, and finally for a number of months, having been absent from February to the present time. The metals were used in the shape of a necklace of disks, one and one-half inch by one inch, a dozen being bound around the throat.

THE PRESIDENT referred to the case, similar to Dr. Seguin's, reported by himself and Dr. Wilkin, and described as tic convulsif. He thought the term chorea misleading in connection with this spasm, unless the fact of a large number of kinds of chorea were borne in mind. This spasm was etiologically distinct from the chorea of Sydenham; not only the muscles of one side, but associated muscles, such as the respiratory muscles, were affected.

Referring to Dr. Seguin's suggestion of a cortical discharge, he would add that Hughlings Jackson places the centre for ejaculatory language also in the foot of the right third frontal convolution.

DR. KELLOGG inquired whether Dr. Seguin's case differed in any way from the

CASES OF BARKING COUGH

known to be epidemic in some instances. In a Philadelphia boarding-school there had been a dozen cases at one time. They had been reported by Dr. Cohen. The sound made was the same.

DR. SEGUIN said that it should be borne in mind that the noise made in his case was but a degenerated form of the obscene utterances, or coprolalia, of four or five months ago. The speaker had seen several cases of barking, snorting, and hiccoughing chorea. He recalled a case from Kentucky, referred to him by Dr. Sayre, in which a sneeze, a snort, and a cough seemed combined. He did not consider this case identical with cases of that character.

DR. KELLOGG read a paper (see p. 106) upon

THE LARYNGEAL SPASM OF MUSICIANS AND SPEAKERS.

DR. STARR inquired why the condition described was not identical with that of hysterical aphonia. In the case of the singer referred to, certain co-ordinated movements of cortical origin were impossible. In hysterical aphonia all co-ordinated movements of cortical origin were impossible. Hysterical aphonia seemed to be the same condition exaggerated to suspension of all the functions of the cortical centres for the larynx.

DR. FISHER had had no experience with this affection of the larynx, but supposed it analogous to the similar affections of the face, lips, and tongue. He recalled the case of a man who had difficulty in talking. He did not stutter, but was unable to make the muscular movements necessary to form words.

DR. SEGUIN referred to the fact that early impairment of the laryngeal movements in the cases referred to was analogous to that of other professional movements, and should, he thought, be referred to a progressive lesion of the cortex, interrupting automatic associated paths, rather than to mere strain from muscular application. He referred to a pianomaker in the conscious stage of general paresis in whom this symptom was prominent.

DR. DANA stated that three cases similar to Dr. Kellogg's had been reported in literature. The first was that of a gentleman, aged forty-five, who had attacks of laryngeal spasm when attempting to use his voice professionally. These became more violent and were accompanied by dyspnœa; he could sing what he wished to say. In another case, reported by Dr. Hartman, a clergyman could only speak comfortably in a whisper. He suffered from spasm whenever he attempted a loud voice. A third case had been reported as one of "neugophonia."

DR. KELLOGG had no doubt of the analogy of spasmodic affections of the larynx to those of writers' cramp. Many cases would probably be recognized so soon as attention was directed to the subject. They would be more frequently seen by laryngologists, although belonging to the class of neurological disorders. The spasms might be mild or severe and clonic or tonic in character. They were, however, distinct from the expiratory spasm of laryngismus stridulus. Beginning general paresis should, of course, always be excluded in the diagnosis of a case. He had referred to the negro-minstrel in whom hyperkinesis and adductor spasm preceded other symptons of general paresis for some months.

THE PRESIDENT then reported for Dr. D. W. Bennett, of Brookhaven, Miss., seven cases of the so-called juvenile type of hereditary progressive muscular atrophy.

They formed the first examples of the type as yet observed in this country, and were striking illustrations of the hereditary character of the disease. The President referred to the fact that recent post-mortem observations had shown that there were two classes of progressive muscular atrophies, those of spinal and those of muscular origin. Omitting the pseudo-muscular hypertrophy group, the progressive muscular atrophies of purely muscular origin were grouped clinically into, first, the facial type, described by Duchenne as the progressive muscular atrophy of infancy; second, the scapulo-humeral type, described by Erb under the head of juvenile progressive muscular atrophy; and third, the peroneal type, beginning in the lower limbs, described by Tooth.

Dejerine and Landouzy had shown that the first and second classes were often united. Dr. Bennett's cases belonged to the scapulo-humeral type. The other cases referred to by the American observers, Dr. William A. Hammond and Dr. Osler, had belonged to the third or peroneal type.

In all of Dr. Bennett's cases the disease began in the

shoulder-girdle, attacking first one arm and then the other. It progressed very slowly, the average duration being forty years. The atrophy was limited in the last two generations to the shoulders and arms. In the first generation it had affected finally the lumbar and thigh-muscles. The health, apart from the atrophy was perfectly good. The disease was transferred to the third generation through the female. It became more acute in the last generation. Of three affected in the first generation, only one had children, showing a tendency for the disease and family to die out. There were no fibrillary contractions observed in any of the cases. In the first generation an uncle was born with only one arm. In the second generation there were seven sons and six daughters. Of these, two males and one female were affected. One of the males had children (number not given); the other two affected had no children. In the third generation one female and one male were affected. The former had seven healthy childen. The latter had thirteen children, eleven healthy and two diseased. In the fourth generation, therefore, there are now two affected and eighteen in health.

The President had inquired of a number of neurologists in and about the city without finding any further cases of this type.

Dr. Fisher asked how early the disease developed.

The President replied, in all before the age of twenty-one years. In this, also, it resembled the so-called juvenile type of Erb.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE REPORT OF THE HYDROPHOBIA COMMITTEE—THE DEGREE QUESTION—CHANGES AT THE UNIVERSITY—HOLIDAYS FOR DOCTORS—AN INTERNATIONAL CONGRESS ON INEBRIETY—THE HOSPITAL SUNDAY FUND—CASES OF SUNSTROKE.

London, July 9, 1887.

The report of the hydrophobia commission has caused not a little astonishment among the profession here. The tenor of the report is certainly calculated to excite some surprise. Pasteur's views are by no means universally accepted in this country, and even those who indorse them could scarcely have been prepared for the verdict of the committee. This verdict is an almost unreserved acceptance of Pasteur's theory. The committee have visited Paris, have watched Pasteur at work, and carefully investigated many of his past cases, the subsequent histories of many being followed up to date. Under the direction of the committee Professor Horsley has made experimental investigations on various points. As the result of their labors they enunciate the opinion that inoculations with the attenuated virus from the spinal cords of rabbits do confer immunity from the disease. This conclusion is strongly confirmed by the experiments performed by Professor Horsley in this country.

As to whether inoculations performed after infection with the virus of hydrophobia are curative and arrest the development of the disease the committee are evidently less decided. They have, however, carefully examined M. Pasteur's statistics and cases, and after eliminating every possible source of fallacy they have come to the conclusion that, even if not invariably successful, the method has at least been the means of saving many lives. They devote some space to considering the alleged dangers of the method. Those of Pasteur's ordinary method they regard as *nil*. They admit that the "intensive method" is attended with risk, but point out that this is partly counterbalanced by the fact that in the worst cases it is more efficacious. As preventives of rabies and hydrophobia the committee recommend the destruction, under certain conditions, of all stray dogs; that the keeping of useless dogs should be discouraged, by taxation or otherwise; that the importation of dogs from countries where rabies is prevalent should either be forbidden or only allowed subject to quarantine; and that, where rabies is prevalent, muzzles should be made compulsory, except for sheep-dogs and others similarly employed. The latter plan was carried out very extensively during the hydrophobia scare of last year. A police-order was issued applying to the whole of the metropolis. The destruction of stray dogs was at the same time carried out on a large scale, to the great comfort of many Londoners—especially those residing in the suburbs. After the report of the hydrophobia committee these orders may not improbably be renewed and extended. The committee remark that, should the protection by inoculation prove permanent, rabies could be suppressed by inoculating all dogs. They are careful to say that they do not think either that all dog-owners would adopt it or that it could be enforced on them. But for this remark one might be tempted to think the committee are intent on a joke. Supposing the procedure to be infallible, would it be possible to carry it out so thoroughly that no dog escaped? To do so would necessitate the establishment of several thousand public vaccination stations for dogs.

The degree question moves slowly onward. The Colleges of Physicians and Surgeons have agreed to combine and ask for a charter to confer degrees in medicine and surgery, and have refused to act in concert with University and King's Colleges in the matter. University College is therefore applying for a charter on its own account. This step was foreshadowed some time since by the part Professor Lankester and others took in the discussion on the subject. University College is, however, a house "divided against itself." Many members of its council view the proposed step with disfavor, as tending to injure the existing university in London, and have resigned their seats on the council. These have, it is true, been promptly filled up, but the secessions must tend to weaken the college, and where opinion is so divided, it is tolerably clear that the government is not likely to take any very decided step.

Concurrently with the changes in the council, but altogether independent of them and bearing no relation to them, numerous changes in the teaching staff have been going on. The retirement of Professor Williamson and Dr. Graily Hewitt, and the death of Dr. Wilson Fox, have caused vacancies, and a readjustment of professorial chairs has been going on. One result of this is that Mr. Victor Horsley, F.R.S., now becomes Professor of Pathology. Mr. Horsley may certainly be congratulated on the distinguished position he has attained. He is only about thirty years of age, and it is only six years since he took his degree at the University of London. He has held the position of Professor-Superintendent at the Brown Institution for some years.

The tropical heat from which we have been suffering during the past few weeks suggests the welcome reflection that the holiday season is at hand. Not to all alike though will it come. Many unfortunate practitioners will be unable to get away from the cares of practice until late in the autumn, and then only for a brief period. Some make a sort of compromise by going a little way from town and coming home for a day or two at intervals. Those who are able to go away for a long spell—say for two or three months at a time—and leave all cares behind during that period, are the few and far between. The late Sir Henry Holland took his annual holiday of three months, and kept up the custom for years, and a distinguished living obstetric physician does the same; but the inevitable loss of practice is too much for most physicians to face, and for most general practitioners the expense of a prolonged tour renders it out of the question. In Sir Henry Holland's case he

avoided holiday practice, but some physicians visit the Continental spas, and sometimes some of their patients make a point of accompanying them so as to continue under their treatment. A venerable physician of my acquaintance remarked once—speaking of holidays—that he formerly knew a medical man in very extensive practice who made a point of spending one day a week out of town. However numerous or important his engagements might be, he would never see anyone on a Wednesday, but would drive out in his carriage some little distance into the country and enjoy the *dolce far niente*. To this periodical recreation my friend attributed in a large degree the preservation of the health of the medical man in question. He carried on for years a large practice without ever being laid up by illness. At present the holiday season is for most of us merely an expectation. Realization has yet to come. In the meantime, in spite of the abnormal heat, most of the London doctors are going about their work as usual, and evince a great disinclination to depart from the ordinary garb of civilization. Black coats and tall hats still prevail. I have, it is true, ere now seen a hospital physician going his rounds in an alpaca coat, and, calling on a West End surgeon during consultation hours, have found him clad in a thin serge jacket; but these are merely the exceptions that prove the rule.

An international congress on inebriety and the special treatment and legislation required for inebriates was held on Wednesday last at the Westminster Town Hall, and was numerously attended.

The collections this year for the Hospital Sunday Fund have already realized about thirty-six thousand pounds. There are still some more to come in.

Cases of sunstroke are reported from various parts of the country.

ILLEGITIMACY AND CATHOLICISM.

To the Editor of The Medical Record.

Sir: In the editorial, "Illegitimacy in Europe," in a recent issue, I find quoted an opinion of L. A. Bertillon, that Roman Catholicism is the great coefficient of illegitimacy in Austria.

There is no one more opposed than I to the introduction of religious controversy into the pages of a medical journal; but since you have seen fit to publish the opinion referred to, I am warranted in claiming the privilege, even in a humble way, of defending the Catholic Church from this most unjust imputation.

When you quoted Bertillon's statement, why did you not also give his proofs? Was it because he had no proofs? I strongly suspect that the latter question is the only answer to the former. If that be so, there is no fair minded-man who will not doubt the accuracy of Bertillon's figures. The animus is patent; the wish in the statistician's heart is father to the thought.

In placing "Austria" in parenthesis you would, perhaps, have us draw the inference that the influence of the Catholic Church in that country is altogether exceptional; in fact, that she pursues one policy (of evil) in Austria, and another (of good) in the other countries in which she holds sway. It may be, however, that I misinterpret your use of the parenthesis. Be that as it may, I am happy to find that the same editorial contains, to some extent, though not to the extent that justice and fair play demand, a refutation of Bertillon's assertion. In the statistical list of illegitimacy in different countries therein contained, I find that the ratio of illegitimates to legitimates in Catholic Italy and Spain is much less than in that heaven-favored, perennial fountain of the good, the true, and the beautiful—Great Britain. I cannot help thinking the ratio you publish of that blessed land is too low. If correct, its lowness can be accounted for only on the principle that Ireland was included, though care is taken to conceal the fact. It is a matter of common observation that whenever England finds occasion to proclaim to the world her renown for martial deeds or her greatness in the realm of intellect, she makes a considerable draft on her "beloved Irish subjects" to swell the number of her eminent men.

It is not to be wondered at, therefore, if, in the present instance, finding the number of her legitimates proportionately small, she, with commendable spirit, falls back on Ireland to augment the quantum of virtue to which she claims title. I am sorry I have not the figures at hand, but I will make the assertion, without fear of contradiction, that in Ireland, whose inhabitants live more under the influence of Roman Catholic teaching than those of any other Catholic country, the ratio of illegitimate to legitimate births is less than in any other civilized land on the globe.

Thos. J. Kearney, M.D.

107 Lexington Avenue, June 22, 1887.

[Our correspondent is in error in supposing that we indorsed the views of Bertillon in the notice referred to. The statistics were compiled by Dr. Holland, and were simply quoted by us. All fair-minded men, we think, recognize the fact that the Catholic Church enforces, with all its power, the observance of sexual purity, and nowhere is the marriage-tie more sacred than among the members of that communion who are faithful to the teachings of their church.—Ed.]

COUNTRY DOCTORS AND THEIR METHODS.

To the Editor of The Medical Record.

Sir: The country doctor, with his traits, trials, and tactics, has furnished your columns some interesting reading. Barring the adjective, the following is fairly within the line:

Was within twelve miles of home, from a long professional jaunt up country. Was hailed from road-side to see a man who proved an old acquaintance, and former—barnacle! This man had a history with me. I knew him to be a mangy, malicious cur, so thoroughly canine that the physiological action of drugs on man didn't apply; who boasted a disbelief in doctors, but was first to call them; able to pay, but wouldn't; low by birth, habit, instinctively—just a *brute*, minus caudal appendage, all-fours, and needful hirsute.

At sight of him, however, the old score was forgotten, the soft side of the doctor came up. Plainly the man was ill, very ill, and a present sufferer; the sunken orbits, corrugated brows, pinched visage, and quickened breathing told this at a glance. A little talk developed that he'd had gonorrhœa some years before, degenerating into gleet; had undergone all kinds of handling, the one trouble being obstinate dysuria. For this he'd been burned, cut, and drawn, with aggravation of it all for net results. Some days before came a seizure unusually prolonged and severe, he passing, with great effort, just enough urine "to keep him from bursting," as he expressed it.

Exposing the parts, there presented a well-defined, dusky-red tumor in the perineum, painful, boggy to touch, but without evident fluctuation; œdematous scrotum and vivid red striæ up groin on either side; cyst uncomfortably full of urine. All this, added to general appearance already detailed, with temperature of 103°, and pulse seemingly growing tired of so much hurry, made a case. A No. 8 catheter, obstinately stopping at five or six inches, didn't improve the outlook.

Diagnosis, reluctantly arrived at: deep-seated, close urethral stricture, urinary extravasation, pus, and all that comes of it.

Preferably, 'twas a case for office, hospital—anywhere but the road-side; a case for help, anæsthesia, and appliances. But I was twelve miles in the country, five from nearest doctor, minus chloroform, staff—everything but scalpel, catheter, and things of minor mention. I be-

lieved in pus, but 'twas deep and couldn't be just nicked out. Too long delay was for the man to die; to operate, so scantily equipped, was, perchance, to kill him. To gain thinking-room and get topography of situation, sent messenger for five-mile doctor, his chloroform—for all he had that would help. Of course, he wasn't at home! The presumptuous wretch, oblivious of "surgical emergencies," aping the privileges of a freeman, had actually gone fishing! His good wife sent, with a note revealing her husband's depravity, a bottle of chloroform—that was all. But 'twas much in a dilemma, the one horn of which was centrally impaling me—gave me one more hand, at least.

Taking a plucky and fairly intelligent farm-hand into my service, gave him a hasty lesson in administration of chloroform by promptly anæsthetizing my patient. He neld him thereafter to operating-point handsomely. With a silver catheter for staff, so far, I did external urethrotomy without a guide. Dividing integument a sufficient length, on a line with raphe, a second incision passed through fascia, and beneath. No pus, but I believe 'twas there—it *had* to be now! A third and deeper cut now developed it; foul enough, and free for locality. Another incision opened urethra.

My diagnosis confirmed, I proceeded more confidently. Passing soft catheter through wound into cyst, drew off large quantity of offensive urine; reversing beak, it came promptly in contact with stricture, just in front of forward angle of wound. Extending incision last made, with probe-pointed bistoury, the stricture was divided.

Nothing remained but the dressing, which was simple enough—a soft catheter in cyst, brought out at wound, the necessary drainage, half grain morphine in rectum, by means of large capsule, cleanliness, etc.

This last is but a routine expression; to talk of possible cleanliness in the case is to know nothing about it. Luckily, antisepsis wasn't so imperative then as now. Otherwise, less than a regiment of veritable scavengers wouldn't have cleansed the premises and cleared operator of the law. Frankly, things were open to the suspicion of being dirty.

This man, with the further attention given, got well without an ugly symptom. Of course he did—first, because such material, obedient to some occult law governing the "fitness of things," rarely succumbs to other than a special dispensation of Providence. Again, and for some further wise purpose, ingratitude and the seemingly correlevant poetry of motion required a demonstration. So it was. Under the friendly cover of one opportune night, he shouldered his load of sin, together with other mobile effects, and hied him to the far West, there to further swell some fluxional movement by the dumb occupancy of useless space. As if the average doctor isn't always more than glad to take it all out in glory!

This little history wouldn't be complete without the relation of a coincidence.

On the very day I was thus playing Samaritan, a most excellent surgeon came to my little city from a larger, skilfully performed an operation wonderfully like my own, and gracefully pocketed a well-earned fee of $250.

I wish to disavow any real bitterness in the premises; trust I'm too well up in the beautiful theories for that, even in view of the coincidence!

And there's really nothing in all this—wouldn't be, at least, in one's office with a clever assistant and all the *jurantia*. Confessedly, however, I've done worse, with ample means for doing better. But it does give one instance more of how things are sometimes done in the country, net cash assets and all.

Very respectfully,

A. G. Browning, M.D.

Maysville, Ky., May 12, 1887.

Professor Flügge, of Göttingen, has been appointed to a newly established chair of hygiene in the University of Breslau.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 10 to July 16, 1887.

Heger, A., Lieutenant-Colonel and Surgeon. Ordered to Fort Columbus, N. Y. H. S. O. 156, A. G. O., July 8, 1887.

Janeway, J. H., Major and Surgeon. Ordered to Benicia Barracks as Post Surgeon, also as Attending Surgeon at Benicia Arsenal, Cal. S. O. 156, A. G. O., July 8, 1887.

Birmingham, H. P., Captain and Assistant Surgeon. Ordered to Fort Myer, Va. S. O. 156, A. G. O., July 8, 1887.

Woodruff, C. E., First Lieutenant and Assistant Surgeon. Ordered to Fort Mackinac, Mich. S. O. 156, A. G. O., July 8, 1887.

Winne, C. K., Captain and Assistant Surgeon. Ordered to Fort Wadsworth, N. Y. H. S. O. 156, A. G. O., July 8, 1887.

Havard, Valery, Captain and Assistant Surgeon. Ordered to Fort A. Lincoln, Dak. Ter. S. O. 156, A. G. O., July 8, 1887.

Maus, L. M., Captain and Assistant Surgeon. Ordered to Fort Schuyler, N. Y. H. S. O. 156, A. G. O., July 8, 1887.

Girard, J. B., Captain and Assistant Surgeon. Ordered to Fort Lowell, Ariz. Ter. S. O. 156, A. G. O., July 8, 1887.

Poindexter, J. D., First Lieutenant and Assistant Surgeon. Ordered to Camp Poplar River, Mon. Ter. S. O. 156, A. G. O., July 8, 1887.

Macauley, C. N. B., First Lieutenant and Assistant Surgeon. Ordered to Fort Gibson, Ind. Ter. S. O. 156, A. G. O., July 8, 1887.

Byrne, C. B., Captain and Assistant Surgeon. Ordered to Washington Barracks, D. C. S. O. 156, A. G. O., July 8, 1887.

Wilcox, T. E., Captain and Assistant Surgeon. Ordered to Fort Niobrara, Neb. S. O. 156, A. G. O., July 8, 1887.

Lippincott, H., Major and Surgeon. Ordered to Fort Union, N. M. S. O., 156, A. G. O., July 8, 1887.

Cleary, P. J. A., Major and Surgeon. Ordered to Fort D. A. Russell, Wyo. Ter. S. O. 156, A. G. O., July 8, 1887.

Caldwell, D. G., Major and Surgeon. Ordered to Fort Assiniboine, Mon. Ter. S. O. 156, A. G. O., July 8, 1887.

Torney, G. H., Captain and Assistant Surgeon. Ordered to Fort Robinson, Neb. S. O. 156, A. G. O., July 8, 1887.

Reed, Walter, Captain and Assistant Surgeon. Ordered to Mount Vernon Barracks, Ala. S. O. 156, A. G. O., July 8, 1887.

Patzki, J. H., Captain and Assistant Surgeon. Ordered to Fort Huachuca, Ariz. Ter. S. O. 156, A. G. O., July 8, 1887.

Ebert, R. G., Captain and Assistant Surgeon. Ordered to Fort Custer, Mon. Ter. S. O. 156, A. G. O., July 8, 1887.

Pilcher, J. E., First Lieutenant and Assistant Surgeon. Ordered to Fort Monroe, Va. S. O. 156, A. G. O., July 8, 1887.

Gardiner, J. de B. W., Captain and Assistant Surgeon. Ordered to Fort Washakie, Wyo. Ter. S. O. 156, A. G. O., July 8, 1887.

CHAPIN, A. R., First Lieutenant and Assistant Surgeon. Ordered to Newport Barracks, Ky. S. O. 156 A. G. O., July 8, 1887.

FORWOOD, W. H., Major and Surgeon. Ordered to Fort Snelling, Minn. S. O. 156, A. G. O., July 8, 1887.

PERLEY, H. O., Captain and Assistant Surgeon. Ordered to Fort Wayne, Mich. S. O. 156, A. G. O., July 8, 1887.

MATTHEWS, W., Captain and Assistant Surgeon. Assigned as member of Army Retiring Board at Washington, D. C., and relieves Captain J. O. Skinner, Assistant Surgeon. S. O. 159, par. 2, A. G. O., July 12, 1887.

MAUS, L. M., and PERLEY, H. O., Captains and Assistant Surgeons. Ordered to accompany the Eleventh Infantry in changing station from Department of Dakota to Department of the East. S. O. 158, A. G. O., July 11, 1887.

GARDNER, E. F., Captain and Assistant Surgeon. Ordered to accompany the Twelfth Infantry from Madison Barracks to Duluth, and to return with Eleventh Infantry. S. O. 143, Division of the Atlantic, July 13, 1887.

EBERT, R. G., Captain and Assistant Surgeon. Will, in changing station from Fort Hamilton, N. Y. H., to Fort Custer, Mont. Ter., accompany the Twelfth Infantry from Department of the East to Department of Dakota. S. O. 159, A. G. O., July 12, 1887.

WALKER, F. V., First Lieutenant and Assistant Surgeon. Granted leave of absence for four months. S. O. 160, A. G. O., July 13, 1887.

CABELL, JULIAN M., First Lieutenant and Assistant Surgeon. Ordered for duty as Medical Officer at Department of Rifle Camp near Bellevue, Neb., August 1st next. S. O. 66, Department of the Platte, July 8, 1887.

A board of medical officers, to consist of Major J. S. BILLINGS, Surgeon; Captain W. MATTHEWS, Assistant Surgeon, and Captain F. C. AINSWORTH, Assistant Surgeon, is constituted to meet in this city for the examination of a candidate for admission to the Medical Corps of the Army. S. O. 157, A. G. O., July 9, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 16, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	7
Scarlet fever	44	7
Cerebro-spinal meningitis	4	4
Measles	30	10
Diphtheria	103	44
Small-pox	3	1
Yellow fever	0	0

ACTION OF DRUGS IN GASTRIC MOVEMENTS.—Some excellent researches are still in process of conduction by Schütz, on the action of some medicaments on the movements of the stomach. Emetine, tartar emetic, apomorphine, strychnine, in a less degree caffeine, veratrine, chloride of barium, nicotine, and pilocarpine in small doses, act as direct excitants of movements of the stomach, which become spontaneous and of abnormal character (*The Lancet*). Muscarine directly stimulates the terminal ramifications of nerves, in causing generalized contractions of the stomach. Physostigmine, digitaline, scillitine, and helleborine produce an increase in the excitability of the muscular coats in such a fashion that the stomach at a given time is agitated by generalized and prolonged contractions. Actual paralysis of the auto-motor centres has not been observed, but chloral, urethane, morphine, pyrophosphate of zinc, arsenic, as well as nicotine and pilocarpine, in large doses, have caused weakness of the gastric contractions. Paralysis of the terminal branches of the nerves has only been obtained by atropine. Ether and chloroform suppress the excitability of all the innervation apparatus, but only during the time when the stomach is exposed to the direct action of the vapors. During anæsthetic sleep the gastric movements are not influenced.

ACIDS OF THE STOMACH IN HEALTH AND DISEASE.—Drs. Cahn and Von Mering (*Ann. de la Société Médico-Chirurg. de Liége*) have lately been investigating the subject of the acids present in the stomach in health and in disease. They find that: 1. The quantity of lactic and hydrochloric acid in the stomach can be determined. 2. In the healthy subject, hydrochloric acid is found in the stomach half an hour after taking food. 3. Under a diet consisting exclusively of meat, hydrochloric acid alone is found. 4. Under a mixed diet, the stomach, whether healthy or diseased, contains hydrochloric, lactic, and volatile acids, in quantities varying according to the length of time the food remains in the stomach. 5. In fever and anæmia, hydrochloric acid may be wanting; but it is always present in amyloid degeneration, and it is only exceptionally absent in carcinoma of the pylorus. Violet of methylaniline does not form a reliable test for the presence or absence of hydrochloric acid in the stomach.

RUMINATION IN MAN.—A communication was recently made by M. Le Juge de Segrais to the Société Médicale de l'Elysée concerning rumination in the human subject. The author records a case, observed by Johannesen, of a peasant, aged twenty-seven, who was subject to frequent epistaxis. He chewed his food imperfectly, and it returned to his mouth automatically from five to fifteen minutes after meals; he then masticated it a second time, the proceeding being attended with a pleasurable sensation. Rumination lasted from fifteen to forty minutes. After a slight meal, or when the man was angry, these phenomena did not appear. Recently the patient suffered from dyspepsia, with tenderness in the epigastric region. The stomach was washed out and the indigestion was relieved, but the rumination continued. The case observed by M. Le Juge de Segrais himself differed from the one above described in that there was no second mastication. The patient, a child, aged eleven, had contracted the habit of causing food to return into the mouth, in order to renew the pleasure of anything the taste of which he liked. In order to effect this, he first recalled the taste of whatever he had most enjoyed in his meal, then held his breath, and, by contraction of the abdominal muscles, brought the particular thing which he wished to taste again up into the mouth; he occasionally did this a second time. On examination, the stomach was found to be slightly dilated, but made no rumbling sound; the child was pale and rather anæmic. His parents had tried every means of curing the habit. When a young child he lived in the country, and milk was his principal article of diet; the stomach became overloaded, and regurgitation ensued. The child became accustomed to these regurgitations, which finally caused a pleasurable sensation, and the habit of rumination was thus established.—*Journal de Médecine de Paris.*

THE CHINESE AND COLD BATHS.—In the northern parts of China it is the custom to use only warm water for bathing purposes, and an attempt, which was made not long ago, to induce the people to use cold water, for the face at least, on the ground that it was more conducive to health, was strenuously opposed by the people, who are accustomed to look on cold water as a medicinal agent, and to be used only in cases of great necessity.

6. **Medi-scalenus.** ["Scalenus medius."]
7. **Post-scalenus.** ["Scalenus posticus."]

These muscles bend the neck forward, bend the head forward upon the neck, and raise the ribs. No. 4 is strictly vertebral (prevertebral); but its connection with "anterior tubercles" of transverse processes of cervical vertebræ, that is, with pleurapophysial elements, shows its intimate relation with the scalene or costo-vertebral muscles, Nos. 5, 6, and 7. The three upper muscles, Nos. 1, 2, and 3, are cranio-vertebral. These are innervated from the upper cervical nerves which form the *cerviciplex;* more exactly, by three branches from the first cervical nerve, before it joins the plexus. The four lower muscles are innervated from the lower cervical plexus or *brachiplex;* but the scaleni also get some supply from higher up. The *lateri-rectus*, or "rectus lateralis," extending from the transprocess of the atlas to a transverse portion of the occipital bone, is by position like an "intertransverse" spinal muscle; but it is hypaxial, not epaxial.

It may be observed, that those muscles of this group which are supplied from the lower cervical nerves are innervated by branches given off *before* these nerves are plaited into the brachiplex.

IV. THE MUSCLES OF THE CHEST.

(*a*) *Innervated by the phrenic nerve, etc.*

1. **Diaphragma.**

The most remarkable and important voluntary muscle of the body, primarily innervated from several *cervici-spinal* nerves, far from the site of the muscle itself; also from several lower intercostal or *thoracispinal* nerves, and moreover from the diaphragmatic *sympathetiplex.* The physiological activity of the muscle is as extensive and diverse as its innervation, being concerned in respiration, circulation, parturition, and defecation.

(*b*) *Innervated by upper intercostal (suprathoracic) nerves.*

2. **Extracostales.** ["Intercostales externi."]
3. **Intracostales.** ["Intercostales interni."]
4. **Infracostales.**
5. **Sterno-costalis.** ["Triangularis sterni."]

These are among the many muscles of respiration. They are all more or less perfectly intercostal, that is, represent myocommas between and separated by ribs. The "upper intercostal nerves" are a convenient grouping of the superior set of *thoracispinal* nerves, being those mainly confined to the thorax. The *supracostales* or so called "levatores costarum" are innervated by posterior, not anterior divisions of the *thoracispinal* nerves, and are therefore epaxial. (See muscles of the back.)

V. THE MUSCLES OF THE BELLY.

Innervated by lower intercostal (infrathoracic) and lumbiplexal nerves.

1. **Extrobliquus.** ["Obliquus abdominis externus."]
2. **Introbliquus.** ["Obliquus abdominis internus."]
3. **Transversus.** ["Transversalis abdominis."]
4. **Quadratus.** ["Quadratus lumborum."]
5. **Intrarectus.** ["Rectus abdominis."]
6. **Extrarectus.** ["Pyramidalis."]
7. **Cremaster.**

Muscles of respiration, parturition, and defecation, and likewise flexors of the trunk. They are closely related to intercostals, chiefly differing in not being broken up into myocommas by intervening ribs. Their innervation corresponds to that of the intercostals, being from successive lower *thoracispinal* nerves and some of the *lumbi-spinal* nerves from the *lumbiplex*, as the "ilio-hypogastric," "ilio-inguinal," and others.

VI.—THE MUSCLES OF THE PERINÆUM.

Innervated by pudic nerve from sacriplex.

1. **Ani-sphincter.** ["Sphincter ani externus."]
2. **Ani-levator.** ["Levator ani."]
3. **Transperinæus.** ["Transversus perinæi."]
4. **Peni-rector** (or **Clitoridi-rector**). ["Erector penis" (or "Erector clitoridis").]
5. **Urin-accelerator.** ["Accelerator urinæ."]
6. **Urethri-pressor.** ["Compressor urethræ."]

A very special group of muscles developed in connection with the urogenital and digestive systems, innervated by the pudic or perinæal nerve from the *sacriplex.* Though attached to the hip-girdle, these muscles are not otherwise related to those of the posterior extremity.

VII.—THE MUSCLES OF THE TAIL.

Innervated by coccygeal nerves.

1. **Coccygeus.**

This is a *hypaxial* muscle; it is *axial* in so far as it agrees with other axial muscles, as those of the abdomen, which are, nevertheless, attached to the hip-girdle; in which latter respect the coccygeus is *appendicular.* It is also the only vestige in man of various large muscles which in some other animals pass from the *coccygispinal* or caudal region of the *spinicolumn* to the pelvis, to the thigh, or even to the leg below the knee. For the present we let it stand by itself.

C.—HYPAXIAL APPENDICULAR MUSCLES.

Innervated by anterior divisions of spinal nerves (or by the accessispinal nerve); and appendicular.

These are the muscles of the limbs, obviously divided into those of the Anterior Extremity, fore-limb, or arm, and those of the Posterior Extremity, hind limb, or leg.

VIII.—THE MUSCLES OF THE ANTERIOR EXTREMITY.

Innervated by the accessispinal nerve and by the brachiplex.

1. CRANIACROMIAL GROUP.

Innervated by the accessispinal nerve.

1. **Sterno-cleido-mastoideus.**
2. **Trapezius.**

Notwithstanding the partial sternal insertion of one of these muscles, they are incontestibly appendicular muscles of the anterior extremity. They are scarcely more than parts of one great *craniacromial* muscle by which the shoulder-girdle, and so the whole fore limb, is attached to the head. The great extent of the trapezius also attaches the limb to a large part of the *spinicolumn*. The only other attachment of the fore-limb to the head is slight and incidental, by means of the omo-hyoid, which belongs to the hyoidean group. The prime and main innervation of the *craniacromial* group is by the *accessispinal* nerve, which, it may be observed, arises from the *spinichord*, low down in the cervical region, opposite the *brachiplex*, whence the fore-limb derives most of its nerve-supply. The great length and breadth of these craniacromial muscles attracts additional innervation from some other sources, notably from deep external branches of the *cerviciplex*.

2. THORACACROMIAL GROUP.

Innervated from lower cervical nerves before these form the brachiplex.

1. **Clavicularis.** ["Subclavius."]
2. **Dorsi-scapularis.** ["Rhomboideus major" et "minor."]
3. **Cervici-scapularis.** ["Levator anguli scapulæ."]
4. **Costo-scapularis.** ["Serratus magnus."]
5. **Coraco-pectoralis.** ["Pectoralis minor."]

A group well-marked in several respects. In the first place, all these muscles get their nerve-supply from lower cervical nerves before the *brachiplex* is fairly formed. Secondly, they are all "short"[1] muscles, connecting the shoulder-girdle with the neck, back, and chest, none of them going on to the humerus. All the nerves to these muscles come off from the forming *brachiplex* above the clavicle, excepting that to the *coraco-pectoralis*. The *cervici-scapularis* attracts additional innervation from deep branches of the *cerviciplex*, owing to its extension in the neck. The so-called "levator anguli scapulæ" and "serratus magnus" really form but a single muscle, extending from pleurapophysial elements of vertebræ, (that is, from anterior tuberlces of cervical vertebræ in the neck, and from ribs in the thorax) to the vertebral border of the scapula; in some animals they are obviously one indivisible plan of muscular fibres, forming a *musculinteger*.[2] The *coraco-pectoralis* is intermediate between the *clavicularis* and the *pectoralis* ("pectoralis major"); it agrees with the former in position and relations (rib to shoulder-girdle), but is innervated by a *brachiplexal* nerve from a different part of the plexus.

The craniacromial and thoracacromial groups of muscles together move the shoulder-girdle in every direction, but especially upward and backward. The movements are reducible in ultimate synthesis to circumduction about the sterno-clavicular articulation as a pivotal point. The *costo-scapularis* is a powerful respiratory muscle.

3. ACROMIAL GROUP.

Innervated directly from the brachiplex.

In this group the innervation is from the midst of the *brachiplex*, that is, after the plexus is fairly formed, and before it is resolved again into the four main nervous chords which are to go along the arm. The muscles agree with one another, moreover, in all going to the upper part of the humerus, at or near the shoulder-joint. But they come from different origins, as far remote, in man, as the sternum and even the sacrum, as opposite as epaxial and hypaxial regions of the body; while some are "long" muscles, coming from the trunk, past the shoulder-girdle, to the arm, others are "short" muscles, coming directly from the shoulder-girdle to the humerus. This renders it expedient to divide the acromial group into subgroups. On the whole, this group is nearest related to the posterior cord of the plexus.

(*a*) *Pectoral Subgroup.*

1. **Pectoralis.** ["Pectoralis major."]

The great sterno-cleido-humeral muscle, innervated from the upper cord of the *brachiplex*.

(*b*) *Dorsal Subgroup.*

2. **Dorsalis.** ["Latissimus dorsi."]

The great vertebro-humeral muscle. Notwithstanding its enormous extent on the back, this muscle is closely allied with the *subscapularis* by its innervation by the long subscapular nerve from the posterior cord of the *brachiplex*.

(*c*) *Acromial Subgroup.*

3. **Acromialis.** ["Deltoideus."]

An acromio-clavicule-humeral muscle, passing farther along the humerus than any other of the *acromial group*, in position related to the *pectoralis*, by innervation allied to the *infrascapularis;* supplied by circumflex branches from the posterior cord of the *brachiplex*.

(*d*) *Scapular Subgroup.*

4. **Prescapularis.** ["Supra-spinatus."]
5. **Postscapularis.** ["Infra-spinatus."]
6. **Infrascapularis.** ["Teres minor."]
7. **Subscapularis.** ["Subscapularis."]
8. **Teretiscapularis.** ["Teres major."]

These are all scapulo-humeral muscles, and all are "short" muscles, proceeding directly from the scapula to the upper part of the humerus. Those upon the dorsum of the shoulder-blade are innervated by supra-scapular branches from the upper cord of the brachiplex; the rest by subscapular and circumflex branches from the middle or posterior cord of the brachiplex. The *infrascapularis* is related by origin and insertion to the *postscapularis*, but by innervation it is singularly allied to the *acromialis*, an apparent anomaly, not easy to explain. The *teretiscapularis* and *subscapularis* are clearly related to each other both by position and innervation; and in the latter respect both agree also with the *dorsalis* ("latissimus dorsi").

The muscles of the acromial group collectively circumduct and rotate the humerus, besides having sundry other effects.

All the remaining muscles of the anterior extremity are innervated from the four main cords,[1] into which the

[1] "Short" and "long" muscles.—A *short* muscle is one which lies on only two segments of a limb, *i.e.*, passes over only one joint. A *long* muscle is one which lies on more than two segments, and passes over two or more joints. Thus, the coraco-brachialis is a *short* muscle: the biceps-brachialis is a *long* muscle. Short muscles have as a rule but one function, whether of flexion or extension, long muscles, an additional reciprocal function. Thus the antico-brachialis simply flexes the forearm: the biceps-brachialis flexes the forearm and reciprocally extends the arm.

[2] Since this paper was written, we have found in the human subject, and publicly demonstrated, the connection between the "Levator anguli scapuli" and "serratus magnus," by means of anomalous additional slips of origin of the former from several lower cervical vertebræ, so that the two supposed muscles constituted an almost continuous single muscle. In some animals, as the opossum, the two muscles are inseparably one, as pointed out many years ago by Dr. Coues in his treatise on the myology of that animal.

[1] These nerves ought to be renamed. "Musculo-cutaneous" is no distinctive name, for it implies what nearly all nerves do—seek the skin after supplying muscles. Besides, there is another nerve of the same designation in the leg, in nowise related to that on the arm.

brachiplex is now resolved—"musculo-cutaneous," "musculo-spiral," "median," and "ulnar."

4. BRACHIAL GROUP.

Innervated from "musculo spiral" and "musculo-cutaneous" nerves.

These are the muscles which lie upon the upper arm.

(*a*) *Pre brachial Subgroup.*

Innervated by musculo-cutaneous nerve.

1. **Coraco-brachialis.**
2. **Biceps-brachialis.** ["Biceps."]
3. **Antico-brachialis.** ["Brachialis anticus."]

The extensors of the upper arm and flexors of the forearm. Innervation definite, and absorbing all the motor power of the nerve which supplies this group; the *antico brachialis* often attracting some additional supply from the "musculo-spiral" nerve. The *coraco-brachialis* is a "short" muscle, only extending the humerus; the *antico-brachialis* is a "short" muscle, only flexing the forearm, constituting its ulnar flexor; the *biceps-brachialis* is a "long" muscle, scapulo-radial, extending the upper arm, and flexing and also supinating the forearm, of which it is the radial flexor.

(*b*) *Post-brachial Subgroup.*

Innervated by "musculo-spiral" nerve.

4. **Triceps-brachialis.**
   - (4*a*) **Extra-triceps.** ["Outer head of the Triceps."]
   - (4*b*) **Medi-triceps.** ["Middle or long head of the Triceps."]
   - (4*c*) **Intra-triceps.** ["Inner head of the Triceps."]
5. **Anconeus.**
6. **Sub-anconeus.**

The triple extensor of the forearm. The *medi triceps* is a "long" muscle, scapulo-ulnar, flexing the upper arm as well as extending the forearm. The *extra-triceps* and *intra-triceps* are "short" muscles, humero-ulnar. The *anconeus* is a prolongation of the *extra-triceps*. The so-called *sub anconeus* is a slight detachment of the triceps, inserted in the elbow-joint.

5. CUBITAL GROUP.

Innervated from musculo-spiral, median, and ulnar nerves.

These are the muscles of the forearm, which (a) flex the forearm, (b) pronate and supinate the forearm, (c) flex and extend the hand and fingers. The musculo-cutaneous nerve having been exhausted of motor power higher up the arm, there are left only the continuations of three cords from the *brachiplex*. These are practically *radial*, *median*, and *ulnar*. (What is meant here by *radial* is the continuation of the musculo-spiral, giving off its "muscular branches" and dividing into two main branches, the so-called "radial" and the *post-cubital*.) According to our views, the many muscles of the forearm ought to fall in *two* primary regions, as in fact they do.

(1. POST-CUBITAL REGION.)

Innervated from "musculo-spiral" nerve and its continuations.

This is the "back of the forearm," where are situated all the cubital extensor muscles of the hand and fingers, and with these the supinators.

(*a*) *Supinator Subgroup.*

1. **Longi-supinator.** ["Supinator longus."]
2. **Brevi-supinator.** ["Supinator brevis."]

These are "short" muscles, humero-radial. The long supinator arises so high up on the *ectocondylar* ridge of the humerus that it gets its nerve direct from the musculo-spiral: it is more powerful as a flexor than as a supinator of the forearm. The short supinator has its nerve from the *postcubital* division of the "musculo-spiral."

(*b*) *Extensor Subgroup.*

(Metacarpal extensors.)

3. **Extensor longi-radialis.** ["Extensor carpi radialis longior."]
4. **Extensor brevi-radialis.** ["Extensor carpi radialis brevior."]
5. **Extensor ulnaris.** ["Extensor carpi ulnaris."]

(Digital extensors.)

6. **Extensor digitorum.** ["Extensor digitorum communis."]
7. **Extensor indicis.**
8. **Extensor minimi.** ["Extensor minimi digiti."]

(Pollical extensors.)

9. **Extensor meta-pollicis.** ["Extensor ossis metacarpi pollicis."]
10. **Extensor primi-pollicis.** ["Extensor primi internodii pollicis."]
11. **Extensor secundi-pollicis.** ["Extensor secundi internodii pollicis."]

It will help to recall the nine extensor muscles whose tendons pass over the back of the wrist, to group them by threes—three to the metacarpus, three to the thumb alone (including its metacarpal), and three to the other digits. The *extensor longi-radialis* arises so high up on the humerus that it gets a nerve direct from the "musculo-spiral"; but all the rest are supplied from the *post-cubital* division of that nerve after it has given off the radial. All the extensors of the thumb and forefinger arise from the back of the forearm, and are *cubiti-digital;* all the others from the *ectocondyle* of the humerus; and these are either *humero-metacarpal* or *humero-digital.*

(2. ANTECUBITAL REGION.)

Innervated by median and ulnar nerves.

This is the "front of the forearm" where are situated all the cubital flexor muscles of the hand and fingers, and with them the pronators.

(*a*) *Pronator Subgroup.*

1. **Tereti-pronator.** ["Pronator radii teres."]
2. **Quadrati-pronator.** ["Pronator radii quadratus."]

These are "short" muscles, humero-radial and ulno-radial; both are innervated from the median, the round pronator directly, the square pronator by a branch from the *antecubital* nerve.

(*b*) *Flexor Subgroup.*

(Metacarpal flexors.)

3. **Flexor radialis.** ["Flexor carpi radialis."]
4. **Flexor palmaris.** ["Palmaris longus."]
5. **Flexor ulnaris.** ["Flexor carpi ulnaris."]

(Digital flexors.)

6. **Flexor perforans.** ["Flexor profundus digitorum."]
7. **Flexor perforatus.** ["Flexor sublimis digitorum."]
8. **Flexor pollicis.** ["Flexor longus pollicis."]

The bulk of the flexor system is much greater than that of the extensor, but the muscles are fewer by three, and in only two sets instead of three sets. Thus there is but one radial carpal flexor, whereas there are two radial carpal extensors. There is but one pollical flexor, to offset three pollical extensors. There is no individual flexor of the index or little finger to offset the respective extensors of these digits; but all the digits except the thumb have two sets of flexors collectively, "sublime" and "profound," or *perforatus* and *perforans*. There is also a gain of a palmar flexor, to which there is no corresponding extensor.

The innervation of this whole region is mainly from the median, either direct, or through its antecubital branch. This nearly exhausts the motor power of the median, leaving very little to supply to the hand. The *flexor ulnaris*, as would be expected, is innervated from the ulnar nerve. The case of the *flexor perforans* is interesting, its supply being from *both* median and ulnar nerves, indicating that it is a compound muscle. The real division of the deep flexor system would appear to be radial and ulnar; that is, the deep flexors of the thumb and of the index and middle finger would form one division, innervated from the median; and the ring and little finger flexors would form the other division, innervated by the ulnar nerve. Such a view is borne out by the innervation of the four accessory muscles of these tendons, the lumbricales, whereof the two outer, or first and second lumbricales, belonging to index and middle fingers, are supplied by the median; whereas the other two lumbricales are supplied by the ulnar.

To sum the motor power of the four main nerve-trunks of the fore limb it may be said: (a) that the "musculo-spiral" presides over the whole extensor system of the limb; (b) the "musculo-cutaneous," over the flexor system of the upper arm; (c) the median, over the flexor system of the forearm, with some assistance from the ulnar; (d) and the ulnar, over the flexor system of the hand, with some assistance from the median.

6. MANUAL GROUP.

Innervated by ulnar and median nerves.

These are the muscles which lie wholly in the hand, and subserve the movements of the fingers. They are all palmar, though certain interossei are sunk so far between the metacarpals as to be best seen from the back of the hand. They constitute adductors and abductors of all the digits; short flexors and extensors of all the digits (except that the thumb has no such extensor), with certain additional short flexors of the thumb and little finger. The extensor function is confined to the dorsal interossei; it is only incidental to their adducting and abducting office, and its exhibition is only partial.

(*a*) *Thenar Subgroup.*

1. **Opponens pollicis.** ["Flexor ossis metacarpi pollicis."]
2. **Abductor pollicis.**
3. **Adductor pollicis.**
4. **Breviflexor pollicis.** ["Flexor brevis pollicis."]

Muscles of the ball of the thumb. Nos. 1, 2, and outer head of No. 4, from median nerve; rest from ulnar nerve. The *breviflexor* may be two muscles, of which the outer head is related to the abductor, the inner head to the adductor.

(*b*) *Lumbrical Subgroup.*

5. **Accessiflexor indicis.**
6. **Accessiflexor medii.**
7. **Accessiflexor annularis.**
8. **Accessiflexor minimi.**

} ["Lumbricales."]

These are the four lumbricales, ancillary to the tendons of the flexor perforans. They lie all on the radial sides of the tendons they respectively subserve, and their innervation is the same as that of these tendons.

(*c*) *Hypothenar Subgroup.*

9. **Breviflexor minimi.** ["Flexor brevis minimi digiti."]
10. **Abductor minimi.** ["Abductor minimi digiti."]
11. **Opponens minimi.** ["Flexor ossis metacarpi minimi digiti."]
12. **Transpalmaris.** ["Palmaris brevis."]

Muscles of the ball of the little finger: innervation entirely from ulnar nerve. The *transpalmaris* is an uncertain as well as inconstant muscle, agreeing with this subgroup in innervation and position, but differing from it in the direction of its fibres, in which it resembles the outer head of the *breviflexor pollicis* to some extent.

These superficial muscles of the manual group are seen to fall in three subgroups, of four muscles apiece.

(*d*) *Interosseous Subgroup.*

13. **Dorsosseus primus.**
14. **Dorsosseus secundus.**
15. **Dorsosseus tertius.**
16. **Dorsosseus quartus.**

} ["Dorsal interossei."]

17. **Palmosseus primus.**
18. **Palmosseus quartus.**
19. **Palmosseus quintus.**

} ["Palmar interossei."]

These are the four dorsal and three palmar interossei; all innervated from ulnar nerve. They are enumerated from the radial side: the numeral names show what fingers they serve. Thus, the index has a dorsal and a palmar; the middle finger, two dorsals; the ring finger, a dorsal and a palmar; the little finger, only a palmar. The dorsals have their tendons all directed toward the axis of the middle finger: the palmars, all away from this axis. There is no second or third palmar; and there is no fifth dorsal.

IX.—THE MUSCLES OF THE POSTERIOR EXTREMITY.

Innervated from the lumbiplex and sacriplex.

The musculation of the hind limb is very definite and easy to classify, if we regard its innervation, yielding some of the most perfectly neural groups of muscles to be found in the body. Thus the muscles of the front of the thigh are all supplied from one part of the *lumbiplex*, those of the inner aspect of the thigh from another part of the *lumbiplex*, and all the rest of the hind limb from the *sacriplex*.

1. PSOATIC GROUP.

Innervated from upper portions of the lumbiplex.

1. **Parvipsoas.** ["Psoas parvus."]
2. **Magnipsoas.** ["Psoas magnus."]

This is the least satisfactory group. The *parvipsoas*, an irregular and inconstant muscle in man, is particularly unconformable. It is, moreover, vertebro-pubic, stopping short of the hip-joint, and thus not falling in with any muscles of the thigh. The *magnipsoas* is vertebro-femoral, but very closely related to the iliacus in all other respects, as of innervation, function, and insertion. Its nerve-supply is primarily from high in the *lumbiplex*, but it also attracts some from the antecrural part of the plexus, like the iliacus.

2. ILIAC GROUP.

1. **Iliacus.**

An ilio-femoral muscle, thus a "short" one, proceeding from the venter of the ilium to the *entotrochanter;* innervation from *antecrural* nerve. This antecrural nerve is mainly derived from the fourth nerve of the lumbiplex (that is to say, from the old "third" nerve [1]) but has connections both with the nerve above it and the nerve below it. It supplies the *magnipsoas* in part, as well as the *iliacus*, showing the connection of these muscles with the antecrural group.

3. ANTECRURAL GROUP.

Innervation by the antecrural nerve.

1. **Sarti-cruræus.** ["Sartorius."]
2. **Recti-cruræus.** ["Rectus femoris."]
3. **Medi-cruræus.** ["Cruræus."]
4. **Extra-cruræus.** ["Vastus externus."]
5. **Intra-cruræus.** ["Vastus internus."]
6. **Sub-cruræus.**

The muscles of the front of the thigh, or anterior femoral region; a well-defined group, exhausting the motor

[1] It should be here noted that Dr. Coues' renumeration of the spinal nerves counts *seven* instead of the alleged "eight" cervical nerves. Consequently, the so-called "eighth cervical" is with him the *first dorsal*, and each succeeding nerve changes its number by one, the so-called "first dorsal" being his *second dorsal*, etc. See his article in the American Naturalist, xviii., 1884, p. 379.

power of the *antecrural* set of nerves. The "sartorius" and "rectus" are *ilio-tibial*, and therefore "long" muscles, flexing the thigh as well as extending the leg. Extension of the leg upon the thigh is the primary and proper function of the sartorius, its flexion of the leg in the human subject being an acquired peculiarity. The *cruræus* and its subdivisions, inner and outer, are femoro-tibial, and therefore "short" muscles, simply extending the leg upon the thigh. The so-called "tensor vaginæ femoris" has nothing to do with this group.

4. ADDUCTORIAL GROUP.

Innervation by the obturator nerve.

1. **Obturiductor.** ["Obturator externus."]
2. **Pectiniductor.** ["Pectinæus."]
3. **Breviductor.** ["Adductor brevis."]
4. **Longiductor.** ["Adductor longus."]
5. **Magniductor.** ["Adductor magnus."]
6. **Graciliductor.** ["Gracilis."]

Rightly regarded, this is one of the most perfect muscular groups in the body. The innervation of all these masses of muscle is almost exclusively by the obturator nerve, including of course its accessory, and thus primarily from the fifth and last—the old "fourth"—nerve of the *lumbiplex*. The *pectiniductor* seems to attract a little supply from an antecrural source, and the magniductor, owing to its great size, steals a little from the sciatic. The trouble has been, that this group has never before been properly put together, the *obturiductor*, the so-called "obturator externus," having always been grouped with the "obturator internus," with which it has nothing to do, instead of being recognized as one of the adductors. Excepting the *graciliductor*, these adductors are all *pubo-femoral* or *ischio-femoral*, and therefore "short" muscles. They extend down the thigh-bone to an increasing extent from the insertion of the *obturiductor* in the *cctotrochanter* to that of the *magniductor* in the *entocondyle*. The *graciliductor* is *pubo-tibial*, a "long" muscle, and therefore flexes the leg on the thigh as well as adducts the limb.

5. GLUTÆAL GROUP.

Innervation from upper part of the sacriplex.

1. **Vaginiglutæus.** ["Tensor vaginæ femoris."]
2. **Ectoglutæus.** ["Glutæus maximus."]
3. **Mesoglutæus.** ["Glutæus medius."]
4. **Entoglutæus.** ["Glutæus minimus."]

Nothing has tended to obscure the true character of the glutæal group so much as the location of the *vaginiglutæus* among the muscles of the anterior femoral region. In man this muscle is inseparable from the *ectoglutæus* without arbitrary use of the knife, it being clearly continuous with that part of the great glutæus which is inserted into the *latifascia* of the thigh. Its innervation, hitherto regarded as "exceptional," is now seen to be regular and conformable with that of the other glutæi. The enormous development of the *ectoglutæus* in man makes it attract from the *sacriplex* a nerve of notable size, which has received the special name of "small sciatic." But this nerve comes from the upper part of the *sacriplex* near the origin of the "superior glutæal" nerves which go to the other glutæal muscles. The name "small sciatic" has no special meaning, and makes the upper glutæal part of the *sacriplex* liable to be confounded with the main continuation of the plexus. It would be better to say *supraglutæal* for the nerve which goes to the *vaginiglutæus*, *mesoglutæus* and *entoglutæus*, and conformably therewith to say *infraglutæal* for the nerve to the *ectoglutæus* muscle, which, after exhausting its motor power on that muscle, become cutaneous in the glutæal, pudendal, and postfemoral regions.

5. COXAL GROUP.

Innervation by muscular branches direct from the sacriplex.

1. **Pyriformis.**
2. **Obturiformis.** ["Obturator internus."]
3. **Gemelliformis.** ["Gemellus superior."]
4. **Geminiformis.** ["Gemellus inferior."]
5. **Quadratiformis.** ["Quadratus femoris."]

A neat group, each member of which has its own nerve direct from the *sacriplex*. Of the six muscles collectively called "rotatores femoris," proceeding from the pelvis to or near the *ectotrochanter*, one, the so-called "obturator externus," belongs elsewhere (see above), and two others, the "gemelli," are simply ancillary to the *obturiformis*.

6. POST-FEMORAL GROUP.

Innervation by muscular branches direct from the sciatic nerve.

1. **Bicipitosus.** ["Biceps femoris."]
2. **Membranosus.** ["Semimembranosus."]
3. **Tendinosus.** ["Semitendinosus."]

Another good group, being the muscles which lie along the back of the thigh, tapping the sciatic nerve as it passes by. The *bicipitosus* is as to its long head a "long" muscle, *ischio-fibular*; as to its short head a "short" muscle, *femoro-fibular*. The other two are "long" *ischio tibial* muscles. The group extends the thigh and flexes the leg.

7. PRETIBIAL GROUP.

Innervation from the pretibial branch of the cctopoplitæal nerve.

1. **Flexor tarsi.** ["Tibialis anticus."]
2. **Extensor hallucis.** ["Extensor proprius pollicis pedis."]
3. **Extensor digitorum.** ["Extensor longus digitorum."]
4. **Flexor metatarsi.** ["Peroneus tertius."]

The muscles of the front of the leg, a group all supplied by the *pretibial*, one of two main branches of the *ectopoplitæal*. They are the long flexor system of the foot and the long extensor system of the toes. All their tendons pass over the instep in front of the malleoli—one to the tarsus on the tibial side, one to the great toe, one to the other toes, one to the metatarsus on the fibular side. The latter has been very badly named "peroneus tertius."

8. PERONEAL GROUP.

Innervation from the peroneal branch of the ectopoplitæal nerve.

1. **Longiperoneus.** ["Peroneus longus."]
2. **Breviperoneus.** ["Peroneus brevis."]

These are the only two peroneal muscles proper, lying in the fibular region, their tendons passing behind the *extramalleolus* to sole of foot. They are long extensors of the tarso-metatarsus. The *peroneal nerve* which presides over this group is badly named "musculo-cutaneous."

9. POST-TIBIAL GROUP.

Innervation from post-tibial continuation of the entopoplitæal nerve.

1. **Poplitæus.**
2. **Ecto-gastrocnemius.** ["Gastrocnemius externus."]
3. **Ento-gastrocnemius.** ["Gastrocnemius internus."]
4. **Soleus.**
5. **Plantaris.**
6. **Extensor tarsi.** ["Tibialis posticus."]
7. **Flexor digitorum.** "Flexor longus digitorum."]
8. **Flexor hallucis.** ["Flexor longus pollicis."]

This is an extensive group, which might, perhaps, be advantageously subdivided, according to its innervation

from the entopoplitæus itself—that is to say, from the main poplitæal trunk above the lower border of the poplitæus, and from its continuation below that line as the *post-tibial*. This would practically give us a superficial subgroup and a deep subgroup. The former would consist (a) of the very peculiar *poplitæus*, a "short" *femoro-tibial* muscle whose oblique direction recalls a pronator or supinator of the forearm; and (b) of the very compound *gastrocnemius*, the outer and inner portions of which are perfectly distinct to the heel in some animals, but in man are blended and further complicated by the development of a *soleus* to an extent unknown in other animals; and (c) of a plantaris, vestigial in man, in comparison with its great size in some species. All these excepting the poplitæus have a common insertion by an Achillean tendon in the heel-bone; they extend the whole foot and (excepting the soleus) reciprocally flex the leg on the thigh. The remaining three muscles complete the extensor system of the foot, and constitute the long flexor system of the toes.

10. PEDAL GROUP.

Innervation by an extratarsal branch of the pretibial nerve.

1. **Brevextensor digitorum.** ["Extensor brevis digitorum."]

The only muscle on the instep, representing the short extensor system of the toes.

11. PLANTAR GROUP.

Innervation by intraplantar and extraplantar branches of the post-tibial nerve.

The muscles of the sole are numerous and do not agree well with their innervation by the inner and outer plantar nerves, if we are to treat them in any similar way to that in which the palmar muscles have been grouped: that is, according to their position and relation to the digits.

(*a*) *Digital Subgroup.*

1. **Breviflexor digitorum.** ["Flexor brevis digitorum."]

To the toes collectively, excepting the great toe. Innervation intraplantar. Though confined to the sole this muscle is a *flexor perforatus*, corresponding to that so named in the forearm.

(*b*) *Accessidigital Subgroup.*

2. **Accessiflexor digitorum.** ["Flexor digitorum accessorius."]

3. **Accessiflexor secundi.**
4. **Accessiflexor tertii.**
5. **Accessiflexor quarti.**
6. **Accessiflexor quinti.**

} ["Lumbricales."]

This is the accessory flexor set, ancillary to the tendon of the long *flexor digitorum*. The nerve-supply is nearly conformable, being mainly *extraplantar*, only the lumbricales of the second and middle toes being supplied by the *intraplantar* nerve. But this separation of the lumbricales into two sets, inner and outer, by their nerve-supply, agrees with the case of the palmar lumbricales. We have named the plantar lumbricales to agree with the name accessiflexor, in the first place, and secondly, to distinguish them as going to the second toe, middle toe, fourth toe, and little toe. Each goes to the inner side of the toe and tendon to which it is related.

(*c*) *Hallucal Subgroup.*

7. **Abductor hallucis.** ["Abductor pollicis pedis."]
8. **Breviflexor hallucis.** ["Flexor brevis pollicis pedis."]
9. **Adductor hallucis.** ["Adductor pollicis pedis."]
10. **Transductor hallucis.** ["Transversus pedis."]

The muscles peculiar to the great toe; named in their order from the inner to the outer side of the sole: the inner two supplied from the *intraplantar* nerve, the outer two from the *extraplantar*. It is very convenient to speak of the great toe as the *hallux*, to distinguish it from *pollex*, the thumb, so as to be able to say *hallucis* simply instead of "pollicis pedis."

(*d*) *Minimal Subgroup.*

11. **Abductor minimi.** ["Abductor minimi digiti."]
12. **Breviflexor minimi.** ["Flexor brevis minimi digiti."]

The muscles peculiar to the little toe; innervation *extraplantar*.

(*e*) *Interosseous Subgroup.*

13. **Dorsosseus primus.**
14. **Dorsosseus secundus.**
15. **Dorsosseus tertius.**
16. **Dorsosseus quartus.**

} ["Dorsal interossei."]

17. **Plantosseus tertius.**
18. **Plantosseus quartus.**
19. **Plantosseus quintus.**

} ["Plantar interossei."]

There are four dorsal and three plantar interossei, all with *extraplantar* innervation. They are enumerated from the inner side of the foot; and the numerals show what toes they serve, since the great toe, like the thumb, has none. Thus the second toe has two dorsossei, the *primus* and the *secundus*. The third toe has both the *tertii*, one dorsal, the other plantar. The fourth toe has the two *quarti*, one dorsal, the other plantar. The little or fifth toe has the only *quintus*, a plantar one. The dorsals have their tendons all directed to the axis of the second toe; the plantars, all away from this axis. There is no second or third plantar; and no fifth dorsal. The arrangement is thus exactly as in the hand, excepting that the axial digit is the second toe instead of the third finger.

The total number of plantar and palmar muscles is the same, viz., nineteen. There is the same number of dorsal and plantar interossei of hand and foot, seven; and the same number of lumbricales, four. The peculiar muscles of the thumb and great toe are the same in number, four. There are only two muscles of the little toe, to correspond to four of the little finger (if we count the *transpalmaris* as one of these); to balance which discrepancy the sole has a *breviflexor digitorum*, wanting in the palm (the corresponding perforated flexor being carried up to the forearm), and also an *accessiflexor digitorum*, with nothing to correspond in the palm; thus bringing about the same number, nineteen.

But the foot has a *brevextensor digitorum* on the instep, to correspond with which there is no muscle on the back of the hand.

DIOSCORINE IN HEPATIC COLIC.—A judge of one of our highest courts was reduced to the verge of the grave with frequent attacks of that excruciating malady, *hepatic colic*. He had the best medical advice that Georgia could give; he vainly sought distant watering-places and other physicians; he was a wreck; gave up his business and lost hope. He was advised to take fluid ext. wild yam—dioscorine—by someone, and never after did he have an attack. I do not mean that one dose cured him, but that from the beginning of its use dated the end of his trouble. He is now one of the finest specimens of the physical man that you meet in our city of healthfulness. He imparted this information to me five years ago. My success with the remedy in hepatic colic has been simply all that I expected or desired. It heightens the pain-relieving power of opium during the attacks, and prevents their return when the remedy is continued. I will not worry you with details, but affirm that I have cured cases where parties had suffered for years with oft-repeated attacks.—DR. J. S. TODD, *Atlanta Medical and Surgical Journal*.

A NEW LOCAL ANÆSTHETIC.

By J. HERBERT CLAIBORNE, Jr., M.D.,

INSTRUCTOR IN OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC; ATTENDING SURGEON TO THE NORTHWESTERN DISPENSARY, EYE, EAR, AND THROAT DEPARTMENT, NEW YORK, ETC.

During the past fall Mr. M. Goodman, V.S., in travelling through West Feliciana Parish, La., had occasion to apply a poultice to the fetlock of one of his horses. Having none of the customary means at hand with which to make it, he raked together a number of leaves from the ground, and having saturated them with hot water, applied the mass as a poultice to the inflamed part. After the swelling had arrived at the proper condition, he made a free incision into the part without the horse giving any evidence of pain. It occurred to him that the leaves might have anæsthetic properties; and a few weeks after, having occasion to open an inflamed bursa on the elbow of another horse, he made a similar poultice, applied it as before, and again made the incision without any pain to the animal.

Dr. Allen M. Seward, of Bergen Point, N. J., having obtained, through Mr. Goodman, some of the leaves, made an analysis of them. He found a number of constituents, among them an alkaloid, and having excluded all others as the anæsthetizing element, concluded that this virtue lay in the alkaloid. He made a two per cent. solution of the alkaloid, and settled the point by obtaining local anæsthesia in a cat's eye with several drops. Mr. Goodman informs me that the tree is known in the locality mentioned as the Tear Blanket Tree.

It grows to the height of thirty-five to forty feet, with a diameter to the bole of about eighteen inches and a spread of foliage of about thirty to thirty-five feet. The leaves resemble those of an acacia. The bark is smooth. From the ground up the tree is furnished with clumps of forked spines or thorns, the parent spine springing at right angles from the bough or trunk. Though Mr. Goodman is a native of the region, he has never seen the tree blossom. As fruit it bears pods eight or ten inches in length, flat and slightly curved, containing seeds and a viscid juice.

The spines are very tough and highly polished, and the wood is extremely tough. It grows in clumps and singly, and is abundant in Louisiana.

From the likeness of the tree to the acacia stenocarpo Dr. Seward dubbed the new alkaloid stenocarpin. It would have been better, however, to withhold the naming of the alkaloid until the botanical name of the tree had been known.

Through the kindness of Dr. Seward I was put into possession of two drachms of a two per cent. solution of the alkaloid.

The results obtained under its use are appended below.

On the afternoon of June 25th two drops of an aqueous solution of the alkaloid were instilled into the eye of a rabbit.

In five minutes there was insensibility of the cornea and conjunctiva palpebral and bulbar, so that the corneal epithelium could be abraded and the conjunctiva seized and twisted with forceps without any evidence of pain or sensation from the rabbit.

In ten minutes there was the same insensibility, with slight dilatation of the pupil. The palpebral fissure seemed wider than at first.

In fifteen minutes the palpebral fissure was markedly widened, the insensibility was the same, the dilatation of the pupil increased.

In twenty minutes the dilatation of the pupil was *ad maximum*, the anæsthesia the same; no change in the width of the palpebral fissure.

At the end of forty minutes there was slight sensibility of the conjunctiva, but complete anæsthesia of the cornea. Dilation still *ad maximum* and width of palpebral fissure same.

Throughout the period of observation, that is, after anæsthesia was established, the cornea presented the same dry, glazed appearance as is observed in cocaine anæsthesia.

In thirty-six hours after the last observation, the dilatation of the pupil was still *ad maximum*, the anæsthesia had entirely disappeared, and the palpebral fissure was normal in width. No blanching of the conjunctiva was observed at any time.

Two drops were placed also on the inner surface of one of the animal's ears, and in ten minutes the surface of the ear covered by the drops could be pierced by a scalpel without a cry or movement from the animal. Multiple punctures in the surrounding tissue elicited abundant evidence of pain. As no untoward symptom appeared at the end of two days, I suggested to my friend, Dr. Allis, of Plainfield, N. J., to allow me to put some into one of his eyes. Without any urging on my part, and with a praiseworthy devotion to science, he allowed me.

June 27th.—Three drops of the above-mentioned solution were instilled into his left eye. He complained that they stung a little. Immediately afterward there was slight lachrymation.

Five minutes: Anæsthesia of cornea and conjunctiva complete; reaction of pupil to light, normal; no dilatation; palpebral fissure increased slightly. The doctor complains that there is a "stiff" sensation in the lids.

Eight minutes: Punctum proximum, five inches. States that the lids feel less stiff, but says that the eyeball feels fuller than before.

Ten minutes: Anæsthesia still complete; palpebral fissure markedly increased; no appreciable difference between the pupils.

Thirteen minutes: P. P., five inches.

Fifteen minutes: Anæsthesia same; width of palpebral fissure same; left pupil slightly larger than the right; reaction to light, direct, accommodative, and consensual, normal; pupil seems to be wider from above, and outward, downward, and inward; conjunctiva seems slightly paler.

Eighteen minutes: P. P., five inches.

Twenty minutes: Anæsthesia of cornea and conjunctiva *not* complete; touching with a strabismus hook gives slight pricking sensation. Dilatation increased; reaction to light direct, accommodative, and consensual. Does not complain of any blurring of the vision.

Twenty-three minutes: P. P., six inches.

Twenty-five minutes: Anæsthesia and width of fissure same as last recorded; dilation of pupil almost *ad maximum*.

Twenty-eight minutes: P. P., seven inches.

Thirty minutes: Anæsthesia abolished; left pupil dilated *ad maximum* and uniform; *neither* direct, consensual, *nor* accommodative reaction can be seen. *Right* pupil contracted to pin-head size, and somewhat irregular; no difference between the tension of the two eyes can be detected. Although the right pupil is contracted it reacts to light, directly, in accommodation and consensually. No systemic effect. Pulse, 80.

Thirty-three minutes: P. P., seven and one-half inches.

Sixty minutes: Palpebral fissure less than at the last recording; dilatation of pupil still *ad maximum* and uniform; reaction of pupil to light, direct, accommodative, and consensual, faint. P. P., nine inches.

In the afternoon of the same day the doctor said he was not able to read at all with the left eye; right eye unaffected.

June 28th, 4 P.M.—P. P., twelve inches; dilatation about medium; palpebral fissure normal; the three reactions of the pupil to the light, faint.

June 29th.—P. P., eight inches; pupil slightly dilated; reaction to light, marked.

On the 30th the pupil was normal, with P. P. at five inches.

At no time was there any unpleasant symptom, so that the doctor had no occasion to regret his immolation to science.

In the days following the above experiments a number of foreign bodies were removed from the corneæ of patients, invariably without pain. Usually two drops sufficed, but in one case, in which the cornea was considerably inflamed, four drops were necessary to cause complete anæsthesia. Whenever the conjunctiva was deeply inflamed, it always retained a certain amount of sensibility, which seemed to be in direct proportion to the dignity of the inflammation. Under no condition did the cornea fail to become perfectly anæsthetized to the spud. When the insensibility was wearing off we invariably noticed that the conjunctiva became sensitive before the cornea.

In several cases where more than several drops were instilled the dilatation was alarmingly great; in fact, the merest rim of iris being visible. As far as we know, however, the pupils returned in time to their normal sizes.

A number of cases of conjunctivitis simplex were treated with it also. We invariably noticed some constriction of the vessels, but which by no means approached that caused by cocaine. It was the uniform verdict of the patients that their eyes felt better and clearer after its use.

In two cases of iritis where the iris was tightly bound down, great effect was observed from only two drops. In one case of trachomatous pannus, the pupil was not dilated *ad max.* at the end of an hour, although six or seven drops had been instilled.

We observed irregular dilatation of the pupil in three cases beside Dr. Allis'; one patient, however, had, in the eye treated, partial atrophy of the optic nerve; in this same case we also observed irregular contraction of the pupil in the untouched eye, but not to the pin-head size.

With a view to ascertaining the effect of the drug on the mucous membrane of the nose, my friend, Dr. L. P. Walker, of this city, painted the solution on the mucous membrane covering my right turbinated bone. In ten minutes I was not able to feel the pressure of the probe at all, and had I had my eyes shut, would not have known that he had touched it. Contact of the probe with parts where the solution had not been placed, settled beyond a cavil the correctness of my observation. The doctor told me he observed a slight blanching, but no contraction to speak of. This might be explained by the fact that only very little of the solution was used.

Dr. Walker also placed into my right ear, at my suggestion, four or five drops of the solution. At the end of twenty minutes a probe was allowed to rest upon the drum; at first there was only tactile sensation, but after a few seconds there was slight pain.

Having waited ten minutes more, he touched the drum in various places. I cannot say that there was pain then, but certainly there was the very unpleasant sensation which one has from striking the drum gently with some blunt instrument. At my request, he then touched the drum of my other ear, in which there had been nothing put. The sensation was almost the same, but I think I can conscientiously say that the drum on which the solution had rested was slightly less sensitive than the other. No unpleasant symptom was caused other than a slight deafness from the presence of the fluid on the drum. This passed away as soon as the fluid was allowed to trickle out.

With reference to its anæsthetic effect on the skin, Dr. Seward had informed me that he removed, under its influence, a wart from a young lady's face by cauterization with the pernitrate of mercury, without any pain. Having saturated a thin piece of absorbent cotton with the two per cent. solution of the drug, I placed it on the anterior aspect of my left forearm. At the end of twenty minutes the skin could be pricked with a scalpel without any sensation. In ten minutes more I made an incision of one-half inch in length in the area which had been covered by the drug. In passing through the cuticle there was the faintest sensation; having passed this, there was absolutely no sensation. I placed several drops of the solution in the wound and continued to dissect, I think, about as far down as the thick fascia, without any sensation, save the grating of the knife against the connective tissue.

In further proof of the anæsthetic effect on the skin, I submit the following:

An Irishman of fifty years presented himself at the Northwestern Dispensary with *otitis media catarrh. acuta.* I observed a sebaceous tumor on his forehead, between the hair and the left eye. I suggested to him to have it removed, telling him that I thought it could be taken away without any pain. He consented. A thin piece of cotton was saturated with the solution and tucked over the tumor and its vicinity; in twenty minutes the skin could be pricked without any pain. In ten minutes more I made a long horizontal incision across the tumor, dissected the skin from around the sac down to the bone, and removed it *in toto.* The man sat perfectly still and said nothing during the whole operation, save at one point, where I made a deep sweep into the connective tissue; he merely observed it scratched a little. Several drops of the solution were immediately instilled in the neighborhood, and in a few seconds I continued to the end without another word from him. When asked if it hurt, he said he had often been hurt worse by the scratch of a pin. Passing of suture caused no pain, and the wound, dressed antiseptically, healed by first intention. The patient seemed very much surprised when I showed him the tumor, and expressed himself as dumfounded.

I have made no experiments on the physiological effect of the drug when introduced into the general system. It should be borne in mind that only a limited quantity of a two per cent. solution was used in the above experiments.

From analogy it would be reasonable to expect that the anæsthetic effect would be increased by stronger solutions. In its effect upon the eye it seems to stand midway between atropine and cocaine. Its anæsthetic effect lasts about as long as that of cocaine; its mydriatic effect is greater than that of atropine, while its paralysing effect upon the muscle of accommodation is perhaps as great as that of atropine, reaching its maximum effect in about six or seven hours, and disappearing rapidly thereafter. It would seem to be indicated wherever cocaine is, so far as its anæsthetic properties are concerned, and where atropine is, so far as its mydriatic properties are concerned. In fact, for irides rendered sluggish by inflammation it seems to be superior to atropine, though the duration of its effects, as we have seen, is by no means as great.

In Dr. Allis' case I was not able to detect any difference in tension, even when the pupil was dilated *ad maximum.*

After examining a number of eyes at the same time, I may confidently say that in seven instances I have observed a *diminution* in tension when the pupil was dilated *ad maximum,* though I have not been able to detect it in all cases. If this property can be settled beyond a doubt, it will truly possess a phenomenal characteristic, of peculiar interest with reference to glaucoma. The contraction of the opposite pupil, though it has not been observed in all cases, was marked in several, particularly in Dr. Allis'.

From the foregoing observations its therapeutic value in eye diseases cannot be inconsiderable.

There is no reason to assume that it will not cause anæsthesia of all mucous surfaces as it has been shown to do in the eye and nose. In view of the results obtained by myself, I feel safe in predicting for it a wide field of usefulness in all departments of surgery where local anæsthesia is desired, and it only remains for further experiment to develop all its possibilities.

It may fairly be reckoned as a rival of cocaine.

Dr. Seward informs me that the winter leaves yield seven and a-half grains of the alkaloid to every ten

pounds, while the summer ones yield only five grams to every ten pounds. The supply of the alkaloid is very small at present and the price very high. An ounce of a two per cent. solution costs $6, which would give sixty cents as the cost per grain. These figures remind one strongly of the market value of cocaine soon after its introduction.

130 Lexington Avenue.

SOME OBSERVATIONS ON BOW-LEG AND IN-KNEE, WITH ESPECIAL REFERENCE TO THE QUESTION OF OUTGROWTH OF THESE DEFORMITIES.

By ROYAL WHITMAN, M.D.,

ORTHOPEDIC SURGEON TO THE BOSTON DISPENSARY.

A large proportion of the cases seen at an orthopedic clinic are deformities of the lower extremity (bow-legs and in-knees). Any radical treatment in such cases is especially difficult, because of the firmly held belief among parents that these deformities are outgrown, and even the application of apparatus is objected to or delayed until such treatment is ineffectual. Family physicians usually advise delay, and that authorities differ may be seen by the following brief extracts from three of the many writers on this subject :

"When rachitis has disappeared such amount of curvature may remain as to require treatment. In the great majority of cases this is unnecessary, since, as has already been stated, the curvatures spontaneously disappear with the growth of the skeleton. Only in the leg, curvatures sometimes remain so that the foot is distorted and only the inner or outer border can be placed on the floor. If this remain for years at the same point an attempt may be made to straighten it." [1]

"The curvatures of rachitis often become less marked during growth, but many of them are so severe that they remain for life. These might have been benefited by timely interference." [2]

"Most of our best surgeons are of the opinion that the so-called *vis medicatrix naturæ* is sufficient to correct the deformed leg if sufficient time be allowed for it to regain the necessary strength, hardness, and ability to bear the weight placed upon it. This is a most dangerous error. No time, no natural process, is sufficient to bring a bent bone which, by a diminished quantity of lime-salts, has once lost its original elasticity back to its normal position." [3]

It is evident that the only way this question of outgrowth could be conclusively settled would be by a series of observations on children suffering from these deformities, extending over the entire period of growth. Such observations have never, to my knowledge, been made, and how the authorities who believe in such outgrowth arrive at their conclusions is not stated. Meanwhile, is one justified in allowing the comparatively short time, during which these bent bones can be easily replaced, to go by? I think not, as I shall endeavor to show.

In considering this subject, as to the advisability of treatment, I concluded to make some observations on the prevalence of bow-leg and in-knee among adults, thinking that by comparing such results with the supposed prevalence of such deformities in children, some general conclusions might be arrived at. Aggregations of adults on whom observations might be made, being presumably of a better or worse grade, it was finally decided that the opportunity which presented itself in the streets of Boston would be most satisfactory. This, of course, limited me to adult males, but as the deformities under consideration were more of cosmetic than of medical importance, this did not seem an objection.

These results are as follows :

Number of observations.	Number of adults observed.	Bow-legs.	In-knee.
1	25	6	2
2	25	4	1
3	30	6	1
4	13	1	2
5	65	9	2
6	27	5	..
7	37	9	..
8	23	5	..
9	27	6	..

34	136	21	2
35	47	16	..
36	37	7	1
Totals	2,000	400	32

Thus, according to these observations, the legs of one adult male in five, or twenty per cent., are curved to a greater or less degree, while only one in sixty-two, or .016 per cent., are affected with in-knee.

As to the relative frequency of these deformities in children, no very satisfactory statistics can be obtained. Most observations have been on the prevalence of rachitis, without regard to deformities, among children presented at hospitals for various diseases or injuries.

McNamara states it to be as high as thirty per cent. at hopsitals, and believes it to be as frequent among children of the better classes, induced by the cold, damp climate of England.

Parry found twenty-eight per cent. of children at Philadelphia hospitals affected with rachitis.

Gee, thirty per cent. at London hospitals.

Ritter von Rittershain, thirty-one at the Prague Poliklinick.

Smith, among the children at the various institutions in New York over which he had supervision, found less than ten per cent. affected by rachitis.

I have no data from which to estimate the prevalence of rachitis and its resulting deformities in children, other than by general observation of children in the poorer quarters of the city and at the primary schools, but I am convinced that the proportion of these deformities among children will not exceed, even if it equals, it in adults.

It seems reasonable to suppose that in certain cases bow-leg may be an inherited peculiarity, and not the result of disease. Again, a certain proportion of these deformities are developed during adolescence, as shown by the well-known prevalence of in-knee among the bakers of Vienna, induced by the peculiar strain to which their knees are subjected, and very probably bow-legs may also result from certain laborious occupations.

In considering this question of outgrowth of rachitic deformities, it must be remembered that the upper and lower extremities stand in completely different relations. In the arms, their weight alone tends to rectify it, and the strains

[1] Billroth : Surg. Path. Tenth edition.
[2] O. Lannelongue : Nouv. Dict. de Méd. et de Chir., art. Rachitisme.
[3] John Bishop, F.R.S., etc. : Unters. üb. d. Wesen u. d. Behandlung d. Deformitäten d. Menschl. Körpers.

to which they are subjected also tend in the same direction, but the legs, already weakened by disease, have a constantly increasing weight to bear. It is very possible that the bones may so gain in strength that the deformity may not increase, and as the leg grows longer it becomes less marked. Still it must be remembered that the majority of children one is called upon to treat for such deformities are already from thirty to thirty-six inches in height, and that the curve in a well-marked case of bow-leg, even if lessened one-half, would still remain in the adult a noticeable deformity.

Thus, taking into consideration all possibilities and probabilities, the following will, I think, be considered fair propositions:

1. A bow-legged boy is more likely to become a bow-legged man than a boy with straight legs.

2. If such a proportion of bow-legs exists among adults as would appear by these observations, it would seem more reasonable to treat such cases in children, rather than to trust to nature for their rectification.

3. If these deformities are to be treated, the sooner treatment is applied the better.

At an orthopedic clinic children are rarely seen during the acute stage of rachitis. In my experience, those applying may be divided into three classes—

First, those who have evidently suffered from a severe form of the diseases, with various irregular curvatures of the bones, which are thickened and deformed, usually with marked inequality, between the upper and lower extremities, stunting of the growth, etc.

Second, children with no well-defined history of rachitis, tardy in development, showing slight general enlargement of the epiphyses, with curvatures principally in the lower extremities.

Third, large, active children with curvatures of the lower leg, with no history of rachitis, and, in many cases, no signs of the disease excepting the deformity.

The proportion of cases in these two latter classes is much greater than in the former, from which I infer that the children of Boston are subject to a milder form of the disease than often occurs elsewhere. The worst cases that I have seen have been among Italian and colored children,. especially the latter. I have also noticed a greater proportion of deformities of the leg among adult negroes, though my observations have been too limited to be of any particular value.

In-knee, a much less frequent deformity, I have only considered incidentally. Why rachitis should in one child cause bow-legs and in another in-knee has never been satisfactorily explained. Possibly, in some cases, a weak child in attempting to stand aids itself by pressing the knees together, the feet being widely separated for a larger base of support. This position, combined with lax internal lateral ligaments, with possibly an exaggerated outward bending of the femur, might induce this deformity. It is a much more serious deformity than bow-leg, as interfering more with locomotion, and as tending to produce laxity of the ligaments at the ankle, with flat-foot, a condition often accompanied by more or less pain.

As to treatment, of course the general condition is of the first importance, but, as has already been stated, these cases are rarely seen until they have nearly or quite recovered from the original disease.

If a patient is seen early enough mild forms of the deformity may be remedied by massage with daily bending of the bones, with possibly the application of splints at night, the child being restrained as much as possible from walking. In more advanced cases suitable apparatus may be applied. In moderately stiff bones I prefer the gradual forcible reposition under ether, with retention by plaster bandages. Often the bones crack during the operation, green-stick fractures being apparently produced. Apparatus, which may be applied at the end of a few weeks, is then simply retentive.

In stiff bones, where the external or anterior curves are low down, apparatus is in most cases useless, and osteoclasis or osteotomy should be performed, osteoclasis being safer when children are to be treated at their homes. In-knee can usually be remedied by apparatus; in more severe cases, where it is not considered advisable to perform osteotomy, the epiphyses of the femur may be partially separated and plaster bandages applied, to be replaced by suitable braces at the end of a few weeks.

A CASE OF VISIONS VERY MUCH BENEFITED BY SODIUM HYPOPHOSPHITE.

By F. A. BURRALL, M.D.,

NEW YORK.

My patient is an American widow lady, aged ninety-three, whose general health is in a remarkable state of preservation, who is not addicted to opium or alcohol, and from whom Dr. Roosa skilfully removed a cataract in December, 1885. Previous to the operation she had been annoyed by visions of gayly dressed young women and ill-favored men, who came to her room at night. A stimulant gave her some relief. After the operation the figures persisted in their visits and caused much annoyance. About the beginning of the present year my attention was especially called to her, as her mind was so much disturbed by the presence of these nightly visitors that it was feared lest it might become necessary to place her in an institution for the treatment of nervous diseases. Her nocturnal guests were not composed of "such stuff as dreams are made of." My patient did not, as would a dreamer, regard these figures as imaginary when remembered on the following morning. To her they were real, and she would express surprise that such persons should be allowed to enter a respectable house and invade domestic privacy. One or two dark men and from three to twenty young dark women would come to my patient's room and remain nightly until near morning. The men would sit and look at her, and the young women, clad in light, handsome dresses, and with gay caps and bonnets, would talk in a low tone, and smile, and hang wet flowers over her pictures or doors, lie upon her bed, and try to pass from her room into the one behind it; they were not rude, but would not leave the apartments when ordered to do so. My patient was annoyed not only by this violation of her privacy, but also felt shocked at the unhealthfulness consequent on the presence of so many persons in her room at night. Life was becoming almost intolerable. Stimulants had been administered by a friend, but the effect was unsatisfactory. On the theory that there was a defective cerebral nutrition which might be benefited by the exhibition of phosphorus, I began the administration of sodium hypophosphite, in doses of ten grains, to be given a short time before retiring. The improvement was so immediate that I cannot regard it as a mere coincidence, since the apparitions had been long and constant in their attendance. It was singular to observe that there was a kind of method shown in the manner in which the visions disappeared. Those which had been present at first, were coarse and would not go when ordered away; those which remained after the use of the medicine, were less disagreeable, and my patient told me on January 25th that the previous night there was only one little woman, who was coming down the curtain, but she told her to go away and she obeyed; one man was also there.

By March 16th my patient was experiencing only slight annoyance from the apparitions, but in April her nervous system became somewhat disturbed by the excitement consequent upon a visit of a real relative. The medicine had been discontinued for some time. There had also been considerable constipation, and this seemed to prove a cause of nervous excitement. Her sleep was again disordered; the medicine was again resumed, and once more speedy improvement followed.

At the present time my patient's condition remains re-

markably better than when she first began the hypophosphite. She still has an occasional uncanny guest, but such visitors have been robbed of their power. She treats the subject of visions with comparative indifference.

Since treating my first patient, I have had under my care a gentleman, aged eighty-three, who was delirious at night during an attack of subacute rheumatism. The bromide of sodium did not diminish the delirium, but he became more quiet after taking ten grains of sodium hypophosphite at bedtime. I thought the same dose also proved of service in inducing sleep in the case of a gentleman, aged sixty, who had been consuming an unusual quantity of spirits for several days, and whose insomnia had not been relieved by bromide of sodium.

I do not think it advisable, in our present defective knowledge of the minuter details of cell-nutrition, to explain the action of this hypophosphite in a less general way than by the theory of impaired cerebral nutrition benefited by phosphorus. Those cases in which we change mental action by drugs are among the most interesting in practice.

Macbeth would not have consigned physic to the dogs and left a slur upon our art, lasting as the immortal lines of Shakespeare, if his physician could have given him "some sweet, oblivious antidote" which might "cleanse the stuffed bosom of that perilous stuff which weighed upon the heart."

48 West Seventeenth Street.

Clinical Department.

A MEANS OF FACILITATING CATHETERIZATION IN WOMEN.

Dr. G. H. Kemp, of Barnesville, O., reports the following case: "Mrs. B. B——, aged twenty-six, primipara, of delicate habit and nervous temperament, gave birth to a child after a protracted and rather severe labor. A couple of days later the patient complained of retention of urine, and examination showed her to be suffering from considerable local irritation and feverishness, with symptoms of pelvic cellulitis. In the course of a few minutes a catheter was introduced and the patient relieved of the urinary difficulty. The next evening the patient was found to be again suffering from retention of urine. The vagina, urethra, and neighboring parts were now swollen and very irritable—in fact, so much so that it was found impossible to introduce the catheter. While reflecting on what to do next, it occurred to me to use cocaine. A small compress was saturated with a four per cent. solution and applied to the irritable parts. In the course of half an hour another attempt was made to introduce the catheter, which proved successful. The effect of the cocaine in allaying the tenderness and pain was so decided that the patient complained scarcely at all while the instrument was being used."

A CASE OF PSEUDO-MEMBRANOUS PHIRITIS.

Dr. George Sterling Ryerson, Lecturer on the Eye, Ear, and Throat in Trinity Medical School, Toronto, writes: "The occurrence of such a case as I am about to describe is rare—so rare that I have been unable to find an account of one in any systematic work on the nose at my disposal, although a certain number may be found scattered through the current medical literature. Mrs. A—— called on me by the advice of my friend, Dr. Burns, on April 6th of this year, bringing with her what looked like a shrivelled polypus, which she said her husband had blown from his nose, and she added that he had thrown off several similar bodies. As he was confined to the house from the effects of an accident, I went to see him that afternoon, and found the left nostril hot, tender, and swollen. From it ran a thin watery discharge. The left nasal passage was completely occluded, partly by swelling and partly by a whitish, tough-looking membrane which covered the inferior turbinated bone. He stated that this membrane had formed several times, and that when it reached a certain stage it became loosened, and by blowing hard he could extrude it. I endeavored to open the passage by the application of a four per cent. solution of cocaine muriate, but with only partial success. I gave him Dobell's solution, with two grains of cocaine to the ounce, with directions to spray frequently; also half a drachm of liq. hydrg. bichlor. and five grains of potas. iodid. three times a day. The only change for some days was that the nasal passage was more free, but the membrane still formed, and the nose remained hot and swollen as before. I then ordered thirty grains of calomel in an ounce of vaseline, to be applied freely and externally to nose. This had the effect of reducing the redness and swelling in a few days. I might remark, in passing, that I have found this application of great value in furuncle of the nose. I also cauterized the mucous membrane, after application of cocaine, with a sixty-grain solution of nitrate of silver. Marked improvement shortly took place, and now, six weeks from the onset, the trouble is cured. The causation in this case was obscure. I suspected syphilis, for various reasons which need not be discussed here, but the patient stoutly denied the accusation, although the improvement under mercurials would tend to confirm the suspicion."

A CASE OF MALIGNANT ENDOCARDITIS SIMULATING INTERMITTENT FEVER.

Dr. Andrew H. Smith, Professor of Clinical Medicine and Therapeutics in the New York Post-Graduate Medical School, Physician to the Presbyterian Hospital, reports the following case: "Henry R——, aged twenty, clerk, called on me, January 27, 1887, complaining of gastric trouble and palpitation of the heart, both of which he attributed to excessive smoking. A careful examination of the heart showed only increased force and frequency of the beat. There was no murmur, and no hypertrophy. The same day, after returning home, he had a severe chill, followed by fever and sweating, for which he took quinine. On the 31st the chill was repeated, and on February 1st I was called in. I learned that since some time in the autumn he had been spending nearly every evening in a malarious district near Hoboken, returning late at night to the city. Also, that he was in the habit of smoking cigarettes in great excess. The violent cardiac action still continued, and I found the spleen somewhat enlarged. I ascribed the chills and the enlarged spleen to the effect of malaria, to which there had been ample exposure, and accounted for the cardiac disturbance as due to nicotine-poisoning in a very neurotic subject, and probably made more active by association with the malarial intoxication. A few days, however, showed this view to be incorrect, as the paroxysms observed no regularity in their recurrence, sometimes being absent for two or three days, and then, again, being repeated at intervals of only a few hours. Moreover, they were entirely uninfluenced by the most liberal use of quinine, arsenic, and Warburg's tincture. During the intervals the temperature was sometimes slightly elevated, sometimes subnormal. Urine not albuminous. As the case progressed the chills were accompanied by vomiting, and followed by extreme depression. The sweating was very profuse. The cardiac disturbance became more violent, and at last a systolic murmur was developed at the apex. This was very soft when first detected, but in a few hours became loud and harsh. The febrile paroxysms grew more marked, the temperature reaching 105°. Diarrhœa with tympanites supervened. No spots were found at any time upon the surface. The strength failed very rapidly, coma supervened, and in the last few hours of life inspiration was

embarrassed in a way that suggested laryngeal paresis from cerebral embolism. Death took place within thirty-six hours after the development of the cardiac murmur, the entire duration of the illness being twenty-nine days. An autopsy was not permitted."

NAPHTHOL IN THE TREATMENT OF ENURESIS.

Dr. S. J. Wright, of Tallmadge, O., writes: "I had a case of enuresis, without cystitis or calculus or any pain, occurring in a neurotic lady thirty-four years old. The condition had existed since childhood. No relief had been found in local or general treatment. She had been obliged to rise many times every night for years. The quantity of urine passed each time was small, the total amount for the twenty-four hours being about three pints. A nervous cough had lasted a year in spite of treatment, and, fearing bacterial infection, I gave her a No. 2 capsule filled with naphthol, also using the drug in the form of a spray. The enuresis rapidly subsided during this treatment, although no change was visible in the appearance of the urine. A temporary cessation of the naphthol for a few days was promptly followed by a return of the enuresis, which again left on resuming the drug. She is now free from enuresis, and can sleep better than ever before. Her throat gives her no pain, her cough is nearly gone, and she can omit naphthol without a return of her enuresis."

PUBIC DISLOCATION OF THE FEMUR.

Dr. C. L. Kinnaman, of West Salem, O., reports the following case: "On June 10, 1887, I assisted Dr. A. S. Kinnaman, of Homerville, O., in reducing a pubic dislocation of the hip-joint, caused as follows: A young man, aged twenty, while breaking a colt, was riding at a rapid pace across a bridge, when the colt fell and slid forward, with the man's right leg and thigh under it, acting as a roller. The forward momentum of the animal, acting on the thigh, rotated the head of the femur out of the acetabulum and over the ramus of the pubic bone, resting the neck on the ramus. The right patella was dislocated outward. Both dislocations were easily reduced by manipulation."

IRRIGATION OF THE PLEURAL CAVITY, IN EMPYEMA, THROUGH THE ASPIRATOR-NEEDLE.

Dr. J. P. Esch, of Huron, O., writes: "In the article on 'The Surgical Management of Empyema,' by Robert Abbe, M.D., in your issue of May 28, 1887, I notice the following statement: 'It was long ago proposed to irrigate the cavity through the aspirator-needle with antiseptic solutions, but there is no literature to show that the results are good, and the method does not appeal strongly to practical operators.' In view of the above I venture to give my experience in this direction, which has caused me to form a different opinion. About four years ago I attended a boy, about eight years old, who had empyema in the right side. The first time I aspirated I drew out about twelve ounces of pus. Temporary improvement followed, but the cavity filled up again and I aspirated again, and repeated this operation seven times in the course of a few weeks, withdrawing each time from eight to fourteen ounces of pus. The boy had chills meanwhile, the temperature ranging from 102° to 104° F., and the pulse kept from 120 to 144 beats per minute. I had about made up my mind to make a free incision and insert a drainage-tube, but concluded to irrigate, and after carefully withdrawing every drop of pus I could get with the aspirator-needle, I injected a two per cent. solution of biborate of soda, using about eight ounces. I left the solution in the cavity for five or ten minutes, meanwhile changing the boy's position slightly several times, so as to bring the solution in contact with every part of the cavity, and then withdrew every drop of it as nearly as possible. The cavity did not fill up again after that and the boy made a rapid recovery, and to-day is as strong and robust as any boy of his age. I have since then used the biborate solution in various cases, and always with the happiest results. In one case of hydrocele I had to repeat the operation, and I then increased the strength of the solution to three per cent. Aside from the fact that the results were so much more favorable than I ever obtained with any other method, the operation is almost painless, and in cases of hydrocele I attend to the patients in my office, allowing the patients to go home afterward, simply wearing a suspensory bandage."

NEW AFTER-TREATMENT OF CATARACTS.

Dr. Julian J. Chisolm, of Baltimore, Md., read a paper on this subject before the Ophthalmological Section of the American Medical Association, of which the following is an abstract: His theory—which the practice of the past year at the Presbyterian Eye and Ear Charity Hospital of Baltimore City has sustained—is that when the extraction operation has been well done, and the eyelids carefully closed by a piece of diaphanous adhesive plaster, the eyeball is so protected from any injury from the movements of the patient that no restrictions need be practised. He treats such cases as if the patient presented himself for the treatment of an accidental wound of the cornea. He only closes the eye operated upon, leaving the other open for the guidance of the patient, who is not even put to bed. His only restrictions are to keep the sunlight out of the room, and to prevent the patient from using the open eye in reading. The adhesive strip is kept on the eye operated upon for five days, by which time the corneal wound, kept in perfect position by the tarsal cartilages of the closed lids, is perfectly healed. He finds that where the patient has not been deprived of light, the eye is not sensitive when the thin strap is removed. In this way convalescence is very much expedited, and smoked glasses are not required. Patients, untrammelled in their movements, can take exercise, eat their regular meals, talk to friends, and in this way relieve the tedium of the week's confinement. In the time which had elapsed since the author adopted this liberal method of after-treatment, only one eye was lost after cataract-extraction, and that through contagion (panophthalmitis). Since May, 1886, Dr. Chisolm reports 98 cataract-extractions and 69 iridectomies, treated by light dressings, with a loss of 6 eyes out of the 167. When contrasted with the usual method of dressing and treatment, the difference in results is most marked. Usually the ophthalmic surgeon, fearing that the slightest movement on the part of the patient will be detrimental to the success of the operation, performs the manual while the patient is in the bed in which he proposes remaining during the treatment. After the operation the eyes are closed with heavy compresses, and secured by a head-bandage which shuts out all light, and is designed to support the eye operated upon. The patient is kept for several days on his back, not allowed to turn over on his side; must not eat solid food, and must not converse, for fear that mental excitement will do injury to the eye. The room is kept dark. At the end of eight to ten days the bandages are removed, and the watery, injected, sensitive eyes are protected under dark smoked glasses for several days, or even weeks, while the eye is getting strong. Dr. Chisolm removes all restraint of any kind, and finds not only that he secures much greater comfort to his patients, but increases the percentage of successes. At the recent meeting of the American Medical Association, in Chicago, many ophthalmic surgeons reported successes by this method of treatment, and they stated that they would, for the future, do away with bandages, dark rooms, and restraint after operations for the extraction of cataracts.

A NOVEL TREATMENT OF PLACENTA PRÆVIA.

Dr. John Winslow, of Ithaca, N. Y., writes: "The interest lately shown by your correspondents in the subject of placenta prævia leads me to report a case whose treatment differed from any that I have seen described. Summoned in haste one night to a stout German primipara, I was at her bedside in less than five minutes after the messenger had left it. The blood had already saturated the bed, made a pool under it, and flowed across the room. It was still pouring from the vagina, when, introducing the whole hand, I found the os about the size of a half-dollar, with the presenting placenta so firmly adherent all around that it could nowhere be detached, and too thick and firm to be penetrated by the finger. So, to check the hemorrhage, I closely applied the palm over the os (with the fingers in the posterior cul de-sac, as the patient lay supine), while the external hand over the fœtal breech strongly held the head against the placenta, the lowest part of which was thus firmly compressed. Hemorrhage was impossible, and not another ounce of blood was lost until, after four fatiguing hours of this steady pressure, the os had so far dilated as to allow one edge of the placenta to slip out, forced down by the head, which now of itself compressed the attached portion against the pelvic wall. Delivery was spontaneous and speedy; and the large, thick after-birth showed near its centre a circle some four inches in diameter much thinned and completely blanched. Both mother and child did well."

THE QUESTION OF OPERATION IN PERITYPHLITIS.

Dr. G. W. Davis, of Holyoke, Mass., writes: "I have been very much interested in the paper of Dr. Robert F. Weir which appears in The Record of June 11th.

"I have been led to consider its teachings more carefully because of its (to me) timely appearance. I now have two patients, both convalescent, coming within the class of cases in which I understand we are advised in the paper to operate, and in both of which the question of operation was considered and laid aside. Had the paper been published a few weeks earlier, I fear I might have been persuaded to interfere, and in the light of present facts my patients might have been the worse for it. I, upon the other hand, would have had a case or two of operation to report.

"Case I.—Mrs. W——, aged thirty-four, widow, was indisposed with moderate fever, thought to be possibly typhoid fever of mild type, but not presenting any certain symptoms of this disease. When, after one week of this mild illness, she was suddenly seized with pain in the right iliac region, rapidly followed by extreme tenderness, frequent pulse, increased fever, and the development of a fulness or swelling which was unmistakable, but which could hardly be called a tumor, it was undoubtedly perityphlitic. I first saw the case in consultation at this time. The diagnosis was perforation with local peritonitis and perityphlitis. From this local beginning a general peritonitis was developed of great severity, and the patient's life was despaired of. An unfavorable prognosis was given, but, contrary to our expectations, after some days she very gradually improved, and is now convalescent; the tympanites and swelling or tumefaction are nearly gone. She was treated with opiates, turpentine, antipyretics, stimulants and support, fomentations, blisters, etc.

"Case II.—Miss D——, aged nineteen, weaver in cotton-mill. Recovered two months ago from attack of dysentery. She was taken while at her work, June 7th, with severe pain in right inguinal region; bowels moved several times without cathartic medicine, and when I saw her, June 8th, there was well-marked local peritonitis or typhlitis with tumefaction, pain, and tenderness. Temperature, 103° F.; high pulse, and seemingly a case of well-marked perityphlitis. Morphine sufficient to quiet all pain was given and continued, turpentine stupes, quinine, and ice. After twenty-four hours, allowed liquid diet. This course continued for five days, when the fever subsided, pulse became normal, the pain and tenderness much diminished, the tympanites became less, and the anxious expression of the face gave way to one of repose and quietude. Now, the eighth day from the attack, there is a well-marked perityphlitic tumor, tender to pressure and not movable, but diminishing in size. An enema was ordered two days ago, but castor-oil was given instead, which occasioned a free movement of the bowels with no bad result. The patient is evidently convalescent.

"Cases III. and IV. were both young adult males. Both developed well-marked perityphlitis with all the usual symptoms, as fever, pain, tenderness, tumor, constipation, etc. They were treated with opiates, quinine, with local applications and fomentations, and a generally expectant course. One of these cases suffered a relapse when nearly convalescent, with return of the inflammatory symptoms and increase in size and sensitiveness of tumor, but both patients fully recovered.

"Case V.—Miss M. A——, aged seventeen. Developed a perityphlitic inflammatory tumor, with all the usual symptoms, which was treated in the manner mentioned in the previous cases, but, as suppuration was found to be inevitable, I was about persuading my patient to submit to an operation, when the symptoms suddenly improved, the tumor subsided, the tenderness diminished, the fever became less, and a general improvement commenced. The same day a free evacuation of the bowels occurred, which was natural, except that a good quantity of pus was mixed with the fæces. Traces of pus could be seen for two or three days. The patient rapidly recovered.

"It seems to me that the proposition 'to open all inflammatory swellings of the right iliac region' is too sweeping and liable to occasion unnecessary and harmful interference; as is the further proposition, 'that where general peritonitis is progressing, with any history of right iliac pain, a limited lateral, or a median laparotomy should be made, to explore the region of the appendix, within forty-eight hours from the inception of the disease.' If such teaching had been followed, all of my five cases would have been subjected to operation, and, had they recovered, I should have been an enthusiastic supporter of early operation.

"There can be no doubt that when suppuration is present and no decided contraindications to operation exist, it should be treated by incision and drainage, but there should be a distinction made between cases in which there is no decided tendency to suppuration and those of a suppurative nature.

"I would like to enter a protest against the universal use of the aspirator-needle for exploration in cases of this kind. May not cases that would subside without suppuration be aggravated and become suppurative as a result of the thrusting of an aspirator-needle in several directions into the already inflamed tissues?"

The Great Questions of the Hour are not prohibition and license, or the ascendency of political parties; it is not the adjustment of differences between capital and labor; it is not the hair-splitting and grain-weighing adherence to the code of medical ethics; it is not the fruitless search after specifics; it is the education of the masses in how to live that they may live happily. I hold that that medical man who employs his time and talents in teaching his fellow-men the laws of life and the principles underlying them, is a greater man than he who devises schemes to prolong the lives of an imperfect race.—Dr. J. A. DeArmond, *Iowa State Medical Reporter.*

Progress of Medical Science.

Atropine Injections in Hæmoptysis.—The subcutaneous injection of atropine in cases of hæmoptysis was recommended by Tacke in 1882, and Dr. Hausmann, of Meran, has found it to be a most successful means of allaying recurring hemorrhage from the lungs (*The British Medical Journal*). The great indication is to allow of the formation of a thrombus in the bleeding vessels, as Traube explained, by diminished blood-pressure. The capillary pressure will be lowered when the smaller arteries have their calibre lessened: hence the use of digitalis, restricted diet, and rest. Reflex vasomotor constriction may also be assisted by astringents or the application of cold. In chronic (and passive) cases iron is recommended. Ergotine, turpentine, morphine injections, and alcohol are favorite remedies. In passive hemorrhage from congestion some recommend wine, walking about, and deep respirations; in active hemorrhage, only rest, ice, and morphine. But there are cases which resist all these measures, and in these Dr. Hausmann has found hypodermic injections of atropine wonderfully efficacious. The following examples are given: 1. A patient with cavities in both lungs had hæmoptysis twice daily for six days to an alarming extent. The hemorrhage was then arrested by a hypodermic injection of $\frac{1}{200}$ grain of atropine. After two months the hemorrhage recurred, and was only arrested by recurrence to atropine. 2 A patient at San Remo was troubled with hæmoptysis all through the winter of 1884, in spite of every care, and it only desisted in the summer. Next winter at Meran he was again similarly affected for a long time, till two injections of atropine (of the same strength as above) arrested the attack altogether. 3. In October last year Dr. Hausmann at once stopped severe hæmoptysis in a lady who had been treated in vain for eight days by ergotine injections, turpentine, etc. The quantities of atropine recommended for hypodermic injection in cases of profuse or moderate hemorrhage from the lungs, which resists other means of treatment, vary between $\frac{3}{1000}$ grain to $\frac{7}{1000}$ grain.

Congenital Occlusion of the Pharynx.—Dr. Illera has given an account of a case in which a newly born child could not be taught to suck, and whose mouth, on the introduction of the finger, grasped it like a ring (*The Lancet*). On inspection the middle third and edges of the tongue were found to be connected to the superior alveoli by firm adhesions, which entirely prevented the organ from being depressed. In addition to these adhesions, two little tumors were seen on the palate near the arch of the fauces, which almost occluded the passage into the pharynx, thus rendering swallowing of liquids almost impossible. It was evident, therefore, that unless operative measures were resorted to the child must necessarily succumb very shortly from sheer inanition. The parents, however, though the state of the case was laid before them, refused to permit of an operation till the fourth or fifth day, when they decided to allow it. The author seized the tumors with forceps and cut them off at the base, touching the bleeding surfaces immediately with the actual cautery. The adhesions were then divided, and after the application of a sponge with cold water for a few hours, repeated very frequently, the child was able to swallow some milk quite easily, and ultimately attained complete use of the tongue. Dr. Illera was induced to publish this case, as he once saw a similar case in which the practitioner in attendance had considered the risk of operation too great to be attempted.

Bone-grafting in Cases of Extensive Loss of Substance.—From a child, aged eleven, Poncet removed the entire right tibia excepting the superior articular surface. The portion extirpated was twelve inches long, and but six inches of periosteum was preserved. After several series of grafts a useful tibia permitting locomotion was produced; the repair was complete in the ninth month. The author considers this practice of advantage in extensive losses of bone-substance, such as are observed after acute necrosis of long bones in children and adolescents or after compound fractures, when a considerable portion of bone has been sacrificed, since it will obviate to a certain extent the shortening of the diseased member and, above all, permit the conservation of its functions by assuring the solidity of the skeleton. In infectious epiphyseal ostitis, the resection should not stop with the removal of the necrosed bone, but extend to the neighboring bone, ulna or fibula, taking care to make the section within the epiphyseal cartilage, in order to prevent the growth of this bone beyond its fellow and the resulting deformity. For the success of bone-grafting, certain conditions are indispensable both to the transplanted fragments and the point of implantation. (1) The grafts should be small, not exceeding six to eight millimetres in length and three to four in thickness; they should include the periosteum and be taken preferably from parts of the skeleton where ossification is the more active; whenever possible the bones of the new-born, dead without pathological taint, should be used; limbs amputated in consequence of traumatism may also furnish material for bone-grafts; so also with the bones of young animals. The fragments should be detached carefully with a strong scalpel, never with a saw, in a direct parallel to that of the bone; the surface of the section should be smooth, and present no projecting laminæ. (2) The place of implantation plays an important rôle in bone-grafting. Implantation should be performed in the period of repair of the wound, when the inflammatory troubles have completely disappeared, when the granulations are healthy, vascular, rosy, and suppurating but little, and when the edges have commenced to epidermize. The transplanted fragments probably never grow; perhaps they are even absorbed after a greater or less time; in any case, they enter for a certain time into the formation of the new bone, which they render firm and reenforce after the fashion of stone or brick in a substance capable of hardening. It is probable also that they awaken by their presence osteogenetic properties in the neighboring tissue. Antisepsis of the graft and of the wound is indispensable; so also is immobilization, such as can only be obtained by a plaster splint.—*Annals of Surgery*, May, 1887.

Drowsiness and Dyspepsia.—Drowsiness accompanying digestive troubles is very common (*The Lancet*). The patient is anæmic and irritable, troubled with palpitation and sensation of fulness after meals, caused by flatus. Bowels may be constipated or not. Used to a sedentary life. The principal points, however, to be looked to are the teeth and urine; the former are bad, and the latter scarcely acid, or else alkaline, and often phosphatic. Alkalinity or deficient acidity is probably present in the stomach, and germs from the teeth swallowed in the saliva. In the stomach, as a rule, the trouble commences; hence the distention and, from pneumo-gastric irritation, the palpitation. Pepsine can only act in an acid medium, and so the food undergoes some abnormal decomposition, with the production of gas instead of normal digestion. It is not difficult to imagine that the products of such changes, taken up and passing through the liver into the general circulation, would produce toxic symptoms. The brain, already badly nourished and anæmic, cannot work with blood deficient in oxygen-carrying corpuscles and loaded with morbid products as well. It therefore "sleeps," disturbed, however, by fitful dreams as more or less irritating matter is supplied to it. What should be the treatment of such a condition? Simply supply what is deficient. If there be constipation, a mild aperient—say, ext. cascar. sag., gr. iij., o. m. ante cib. Attend to the teeth. For the alkalinity and palpitation the following: ℞. Acidi hydroch. dil., ♏ xv.; tr. nucis vom.,

℥ x.; tr. calumbæ, ℥ xv.; aquam ad ℥ j.; ter die post cibos, with or without succus taraxaci, ℥ j., or vin. pepsin., ℥ j., as required. Limit smoking. Stop all tea, coffee, cocoa, and hot fluids. Let the patient drink cold water for breakfast, light ale, claret, or water at dinner—say at 2.30—and a light supper at 8 P.M., with the same drink, and no fluid between meals. Nearly finish every meal before drinking. Advise friction with a towel over the abdomen, sufficient out-door exercise, and early bed.

Toxic Effects of Salicylate of Soda.—Dr. Hampeln, of Riga, has published the case of a gentleman, aged sixty, who suffered from chronic catarrh of the bladder, and to whom salicylate of soda, in the daily dose of one drachm was administered. From November 22d to January 5th over five ounces of the drug were taken by the patient. During that period there gradually appeared striking lassitude, drowsiness, unsteady movements, tremor of the hands, loss of attention, failure of memory, weakness of sight, and listlessness. At first a suspicion about incipient dementia was entertained by the author, and shared by a specialist. But then an idea of the possibility that the symptoms could be caused by the salicylate crossed the author's mind, and induced him to discontinue the drug. No change was observed during the first ten days, but during the next fortnight there ensued complete recovery from all nervous symptoms. Dr. Hampeln draws attention to the disproportion between small doses of the drug and the intense effects in his patient. He was able to find in literature only one similar case of chronic salicylism, that by Dr. Mueller, in which a diabetic patient had taken almost five ounces of the drug in nine days.

Fatal Result of Intra-uterine Medication.—Dr. Engström relates the following case in a Swedish medical journal: A woman, aged thirty-seven, had suffered from persistent metrorrhagia. The uterus was retroflexed, but no signs of past or present inflammation could be discovered. It was replaced and scraped out with a Simon's sharp spoon, two small spoonfuls of hyperplastic tissue being removed. A solution of iodine in iodide of potassium at 113°F. was then injected, the relative proportions of iodine, iodide of potassium, and water being 1, 2, 30. No fever and scarcely any pain followed. In five days' time a second injection was used, the temperature being 104°F., and the relative proportions of iodine, iodide of potassium, and water 1, 2, 10. No pain was experienced, and the patient walked up and down stairs. On the evening of the second day, however, a rigor came on, followed by pyrexia, abdominal tenderness, diarrhœa, and convulsions, death occurring two days latter. At the necropsy there were found broncho-pneumonia, chronic œdema of the lungs, encodarditis, and purulent peritonitis. The substance of the uterus was soft, friable, and gray-colored, containing specks of blood and lymph. The peritoneum over the uterus was of a yellowish-red color and covered with puriform matter. The Fallopian tubes and their fimbriated extremities were not dilated or particularly reddened, and the mucous membrane presented no abnormality. The os uteri was too small to admit a fine probe. A large quantity of pus occupied the peritoneal cavity. Dr. Engström does not think any of the injection can have passed into the tubes, still less into the peritoneal cavity, and believes that the fatal peritonitis was due to an extension of the inflammation directly from the uterine wall to the peritoneum.

Rectal Intussusception Due to a Tumor.—At a recent meeting of the Royal Medical and Chirurgical Society (*The Lancet*, May 14, 1887) Mr. A. E. Barker communicated a case of intussusception of the upper end of the rectum, due to obstruction by a new-growth, in which complete recovery ensued, after excision of the intussusception and suture of the cut ends of the bowel. The case narrated is that of a married woman, aged twenty-eight, who for sixteen months had noticed streaks of blood with her motions, and for eight months had been conscious of a foreign body in her rectum. Two or three months before operation the latter had begun to prolapse at each stool, with copious bleeding. There was much constipation, but there had never been any diarrhœa. On examination of the rectum in June, 1886, a mass of new-growth was found surrounding nearly the whole of the apex of an intussusception of the rectum. The reflexion of the rectal wall could be felt about three inches from the anus, so that the apex of the mass belonged to a spot about six or seven inches from the latter. On June 9th Mr. Barker drew down the intussusception and operated, as follows: The left index-finger was passed well into the intussusception and the two layers of bowel were pinched together beyond the growth between the finger and thumb. An ordinary sewing-needle, carrying stout carbolized silk, was then passed through the two layers from the intussuscipient into the lumen of the intussusception and returned, including about one-sixth of an inch of bowel-tissue. This loop was tied firmly, and another stitch was similarly introduced, about one-sixth of an inch from the first, and tied in the same way. By repeating this the whole bowel was encircled with a row of stitches well above the growth. When this had been done, a second row was similarly introduced about half an inch higher up. The whole intussusception was then cut away *en masse* immediately below the lowest row of stitches. Only one small vessel bled, and was tied; the rest of the cut surface was dry. The mass cut away consisted of a nodular mass of adenoid epithelioma, taking up about two inches of the bowel, and with a margin of healthy tissue above it. The patient's recovery was rapid and uninterrupted. A large motion was passed on the sixth day. The patient left the hospital about four weeks after operation, feeling quite well. The rarity of intussusception of the rectum is discussed and some statistics are given. The rarity also of intussusception of the lower bowel produced by cancerous growths is alluded to, the author having only been able to collect eleven such cases. These are briefly described, six of them being either purely rectal or in the sigmoid flexure. Of these six, only four were operated on; the first two by Verneuil, but both with a fatal result. The next excision was performed by Kulenkampff, with an ultimately good result, but a loop of small intestine had been opened in excising the intussusception and a provisional colotomy had to be done. The case now related is the fourth.

Gastric Syphilis and Simple Ulcer of the Stomach.—Dr. Galliard discusses the question of syphilitic disease of the stomach, and the influence of syphilis in the pathogeny of ulcer of that organ (*The London Medical Record*). The existence of syphilitic affections may be shown by clinical or by anatomical evidence. It has been proved by observation that certain gastric troubles, occurring in the course of secondary or tertiary syphilis, may be successfully treated by mercury and iodide of potassium. M. Galliard, however, does not exaggerate the value of such facts, since gastric troubles and hæmatemesis are not sufficient to prove a lesion of the stomach itself. Syphilitic disease of the liver, for example, like ordinary cirrhosis, may cause hæmatemesis. The anatomical signs are divided by M. Galliard into disputable and indisputable; the former are gastric catarrh, hypertrophy of the walls of the stomach, and ulceration due to amyloid degeneration. The true syphilitic lesions of tertiary syphilis are gummata, ulcerated or not ulcerated. The author reports two clear cases of gastric syphiloma. Gastric cicatrices found in syphilitic persons may be due to former gummata or to simple ulcers. They are only of moderate value in diagnosis unless gummata be also present, in which case it would be reasonable to consider the scars evidence of by-gone specific lesions. When, instead of cicatrices, there are found in syphilitic persons ulcers having the characters of Cruveilhier's ulcer, the

question ought to be asked whether the primary erosion was not of a syphilitic nature—whether, for example, its occurrence was not determined by the gastric catarrh of secondary syphilis, or by syphilitic arteritis. It is easy to understand that such an erosion, exposed to the contact of the gastric juice, may be capable of becoming a round perforating ulcer. It is thus necessary to study with great care, both during the period of ulceration and that of cicatrization, the so-called simple ulcers of the stomach when they are found in syphilitic subjects. In this way the pathogenic influence of syphilis on the stomach, perhaps even the characters of ulcerating syphilides of the stomach, may some day be decided; and when the diagnosis has been made, such affections will be amenable to treatment and capable of cure; but at present the diagnosis is surrounded by difficulties.

The Antagonism of Cocaine to Caffeine.—Dr. Martin states that a child eighteen months old drank the contents of a bottle containing eight grains of cocaine in four drachms of syrup of marsh-mallow, which had been prescribed for teething pains. Serious symptoms of poisoning occurred. Another doctor was called in, who prescribed syrup of ipecacuanha. There was slight vomiting, after which a diuretic, composed of acetate of ammoniac and syrup of roots was administered as an antidote to the action of the cocaine on the urinary organs. The general symptoms improved, but there remained considerable irritation of the visual organs, which ceased on the patient taking two spoonfuls of syrup of caffeine. The author asks whether caffeine may be considered as an antidote to cocaine. Dr. Schilling (*American Journal of Pharmacy*) maintains that he has successfully combated the effects of cocaine by means of inhalations of nitrite of amyl.

The Treatment of Hydrocele.—Dr. Tedenat has followed one hundred and fifty patients, whom he has treated by iodine injection, for from six months to five years or more; there were eight recurrences in the first four months, and in all twelve per cent. But if, instead of the more attennated solutions, pure tincture of iodine is introduced, the percentage of recurrence is reduced to two or three per cent. According to the partisans of incision of the scrotum and excision of the tunica vaginalis, recurrence should never occcur; but as a matter of fact it does, sometimes, at least. Bergmann excises the entire tunica vaginalis. The author has performed this operation fifteen times, and all the cases were cured. While he does not know of a death from iodine injections, an accident, which is not rare, consists in losing a drop of the fluid in the scrotum, giving rise to phlegmon; besides infiltration of iodine into the scrotum there may be suppurating perivaginalitis; however, these accidents are of little gravity. Incision doubtless ought to obviate these accidents if it is aseptic, but asepsis is particularly difficult to insure in this region. The true danger of iodine injection is hemorrhagic perivaginalitis; accordingly, he believes that excision should be performed in case of ancient hydrocele with thick and but slightly transparent walls; in ordinary hydrocele, translucid, with thin walls and without calcification, the treatment of election is iodine injection; a small quantity of tincture of iodine should be injected and allowed to remain in the tunica vaginalis.—*Annals of Surgery*, May, 1887.

The Diet of Childbed.—Dr. Rubenstroth (*Memorabilien*) says that every practising physician can easily verify that, in regard to the diet of lying-in women, there still exists an incredible number of prejudices, errors, and fallacies, and that not altogether with the laity alone, but also among midwives and even a large number of physicians. Experience teaches that among the common people traditions endure for a long time and with great tenacity. When more thorough knowledge shows that old teachings are wrong and worthy to be rejected, it often happens that in practice we have not only to fight the folly of the common people, but also the superannuated and erroneous precepts of our medical predecessors. The withholding of a choice and model diet from women in childbed is directly injurious both to mothers and children, on account of the deficiency of nourishment connected with it. Kleinwächter, by weighing and measuring, has shown that by the use of a good and rich fare on the part of the mother, not only does she recover more rapidly from the debilitating influences of confinement, but that children thrive much better and increase much more rapidly in weight. *A priori* it is not easy to conceive how a woman, whose strength has been so extraordinarily taxed by childbirth and lactation, could find herself the better by being robbed of her accustomed nourishment. It is quite obvious that the proper nutrition of the mother must benefit the child. The author is convinced that many a mother, now unable to nurse her child on account of want of milk, would not be so if, from the first day of confinement, she had been richly and strongly nourished. As a consequence, artificial instead of natural nursing has to be resorted to, with the bad results that are so well and generally known. In our country Barker answers the question, what nourishment the lying-in woman should have, in a very clear and simple way: "A lying-in woman should have all the good, nutritious food that her appetite demands and her digestion can control and assimilate." Therefore, it is not a matter of so many days, but of the condition of the appetite and the digestion. If both are found in normal condition, the mothers may have meat and easily digested preparations. In this way they will certainly get along better than if allowed to go hungry. If a good and rational nourishment is a necessity with every lying-in woman, it is an imperative matter when the confinement has been accompanied with great loss of blood or other exhaustive influence. Dr. Rubenstroth has seen women who, from loss of blood during the third stage of labor, had become so weak that they were unable to raise the head without fainting, and who yet, by the use of roast meats and other nutritious diet, were able to be up at the accustomed time, fresh and strong; while by the spare diet so commonly supplied they could only have returned to their household duties in the course of months. Furthermore, if the return of strength is not favored, and pregnancies follow in rapid succession, a condition of anæmia becomes chronic and may last through the whole of afterlife. As soon, however, as lying-in women become convinced of the good effects of abundant nourishment they become enthusiastic partisans of the *régime*, and then often do too much of a good thing. Gastric catarrh produced in this way can certainly cause harm and give the physician a great deal of care.

A Freezing Microtome.—Dr. Isaac N. Himes, of Cleveland, sends a description of a new freezing microtome which will be useful in the examination of fresh specimens, and especially in the demonstration of tissues removed at a post-mortem examination, to classes in practical microscopy. The freezing is effected by the evaporation of distilled ammonia. The microtome is a modification of Dr. Thomas Taylor's freezing microtome. In the latter a freezing mixture of salt and ice is used, the cold salt water being allowed to flow through a hollow chamber upon the flat upper surface of which the specimen to be frozen is laid. In Dr. Himes' modification the ammonia liquid or spray is made to enter a hollow chamber, altered in construction to suit the ammonia method of freezing. The instrument is always ready for use, there is no sloppiness incidental to the use of salt and water, there is no subsequent labor in cleaning up, and the temperature may be made so low that alcoholic preparations may be cut without much soaking to remove the alcohol.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 30, 1887.

THE PRESENT STATUS OF THE QUESTION OF INTUBATION.

THE subject of intubation is still one of great interest, and will justly continue so until its place in therapeutics is fairly established. The glowing expectations excited at first have not been realized, and in some quarters there have come most discouraging reports. Yet it is not an operation which will be discarded. Dr. E. Fletcher Ingals, in an article on intubation in the New York *Medical Journal*, summarizes the present condition of the question as follows :

1. Intubation may be quickly and easily performed, and with but little danger.

2. Friends readily consent to the procedure.

3. There is no necessity of tedious after-treatment, as the tube is kept clear by the respiratory efforts.

4. The results so far are practically as good as those of tracheotomy at all ages, and apparently better in very young children.

5. To secure the best results, great care must be taken to prevent the entrance of foreign substances into the trachea.

6. At present, with O'Dwyer's tubes, the most successful plan is to absolutely prohibit the deglutition of fluids while the tube remains in the larynx. Small bits of ice may be sucked to allay thirst ; soft solids may be swallowed, and fluids may, if necessary, be supplied by enemata, or the tube may be removed to feed the patient, and then be reintroduced.

7. Tubes with smaller heads, designed to rest on the vocal cords, have not yet been used sufficiently often to enable us to speak positively about them. If experience proves that they do not often slip into the trachea, and that they do not injure the vocal cords, they will be especially useful, for they will nearly overcome the difficulty in deglutition, and patients wearing them may eat and drink at pleasure, excepting when paralysis or some other result of the disease prevents closure of the epiglottis.

8. Medical treatment should be carefully attended to after intubation, and we must spare no effort to prevent extension of the disease to the bronchial tubes, or to relieve the dyspnœa which it occasions. I apprehend that successful after-treatment depends largely upon the judicious and timely use of suitable expectorants and respiratory and cardiac stimulants.

9. Though short tubes may be used with good results in some cases, the danger of their becoming filled with pseudo-membrane is so great as to render long tubes preferable.

10. Intubation may and should be practised early, and it does not preclude subsequent tracheotomy.

11. For serious cases of spasmodic croup, and for œdema of the glottis, this will prove a most useful procedure.

12. For the treatment of chronic laryngeal stenosis this method will, doubtless, be of value.

EAR DISEASE AND CEREBRAL ABSCESS.

THE death of the late Professor Schroeder from cerebral abscess, and the recent impetus furnished to cranial surgery by the successful operations of English surgeons, give especial interest to an elaborate paper on "Cerebral Abscess due to Ear Disease," published by Dr. P. McBride and Mr. A. G. Miller in the Edinburgh *Medical Journal* for May and June.

The authors in question have collected forty-four fatal cases of middle-ear suppuration causing intracranial complications. The complications caused are arranged in the following order numerically : Diffuse purulent meningitis, 16 ; thrombosis of sinus, usually the lateral, 10 ; cerebral abscess, usually in middle lobe alone, 9 ; cerebellar abscess, 7. Wernicke, in his work on diseases of the brain, places caries of the cranial bone, and especially the petrous bone, as second in the cause of brain abscess. It will be seen from the figures above given that abscess and meningitis are the two most frequent fatal sequelæ of ear disease, and that the two complications are themselves of about the same frequency.

Since abscess from middle-ear suppuration is not extraordinarily rare, the question whether the modern methods of cranial surgery may not be applied here very naturally arises. So far Dr. McBride can collect only four successfully treated cases, recorded by Schondorff, Truckenbrod, Greenfield, and Gowers and Barker. In the two former, however, there was an external fistula, the surrounding scalp being œdematous and tender. In the last-mentioned case, an abscess of the temporo-sphenoidal lobe was correctly diagnosed by Gowers, and successfully operated upon by Barker. In this instance the point of the trephine was inserted an inch and a quarter behind, and the same distance above, the meatus. Before proceeding to operate on the bone, the state of the opening for the mastoid emissary vein was examined.

An important diagnostic point in distinguishing between meningitis and abscess is that in the latter condition the pulse and temperature are as a rule low, or subnormal at some period at least in the progress of the disease. In cerebral abscess there are the usual signs of focal lesion ; in cerebellar abscess severe occipital headache, distressing vomiting, giddiness, and in cases due to ear disease, absence of bone-conduction are to be expected. Dr. McBride thinks that abscess near, or in communication with, the tympanum, having spread through its roof, is the form that affords the best prospects of treatment. The mode of operation suggested as the best is described as follows : One should make a dissection of the auricle downward so as to define the osseous meatus. When

this has been done, an opening should be made just above and in front of it—a proceeding which exposes the dura mater within a very short distance of the roof of the tympanum, with which the great majority of cerebral abscesses are in intimate relation, without any danger of wounding the middle meningeal artery.

The conclusions reached by the writers are worth recording:

(1) That in a case of chronic middle-ear suppuration, whether the mastoid region be tender or not, opening the mastoid antrum should not be too long delayed if deep-seated pain in the ear be complained of, and if the general symptoms point to head mischief.

(2) That in advanced cases we should attempt to arrive at an exact diagnosis as to the nature of the intracranial mischief, with a view to operative interference.

(3) That we can in most cases detect sinus-phlebitis from the presence of pyæmic symptoms and from local manifestations. Thus, if the lateral sinus be involved, the region of the jugular vein will often be found tender and occasionally corded; if the cavernous sinus be at fault, we should expect œdema of the retina, and around the eye, perhaps also exophthalmus (for further information on this point I must refer to special treatises).

(4) That having excluded sinus-phlebitis the diagnosis may be said to lie between diffuse meningitis and localized abscess.

(5) That the situation of the intracranial suppuration will probably be behind the tentorium if bone conduction be lost, *i.e.*, if the auditory nerve is involved. That, in my opinion, this is also more likely to be the case when there is marked inflammation of the mastoid (*i.e.*, its external and posterior part), than when the pain seems only to proceed from the tympanum; but I have been able to obtain no definite proof of this. The results of aural examination must, of course, be taken together with the general symptoms in localizing the brain lesion.

(6) That the most common seat of localized abscess and starting-point of suppurative meningitis is near the roof of the tympanum.

(7) That we cannot in most cases distinguish positively between localized and diffuse suppuration; but that in cases where pulse and temperature are subnormal, the probability is in favor of localized abscess.

(8) That the point chosen for opening the skull in otitic cerebral abscess should be just above and in front of the osseous meatus.

(9) That such an operation may save a number of cases of localized abscess, and may possibly benefit some in which the suppuration is more diffuse.

(10) That the propriety of exploring the cerebellar region is not so clear, and that this operation should only be undertaken when the presence of pus behind the tentorium is almost certain.

NEW MYDRIATICS.

Despite the emphatic claims for superiority none of the various new mydriatics have supplanted atropine. There are two, however, which deserve some attention and occasional use. These are duboisine and hyoscine.

Duboisine is obtained from the *duboisia myoporoides*, of which it is the active principle. Upon the eye it acts more rapidly than atropine as a mydriatic, and it causes complete paralysis of accommodation. This latter paralysis is prolonged, while the mydriatic effect is shorter than that of atropine. It is also claimed to be less irritating (Dr. William F. Norris), but this is not always the case, and several persons have seen it produce conjunctivitis. De Wecker advises the employment of duboisine in order to get a certain, quick, and complete paralysis of accommodation. In the treatment of synechiæ it is not more efficient that atropine; and collyria of duboisine may cause constitutional effects. These consist of great motor weakness, trembling, and anorexia. Physiologically it acts much like atropine, but is said not to stimulate respiration.

The internal dose is about one-half that of atropine. For instillation the following formula is recommended by Dr. Paul Chéron (*Union Médicale*): ℞. Sulphat. dubois., 0.25 to 0.05; aquæ destillat., 10.00.; to which one can add 0.05 acid. boric.

Hyoscine is the alkaloid associated with hyoscyamine in *hyoscyamus niger*. It is nearly identical with amorphous hyoscyamine of Merck. It forms a soluble salt with HI, HW, and HCl. The bromo-hydrate is the salt most used, it being very soluble in water. It possesses a formula like that of hyoscyamine and atropine, viz., $C_{17}H_{23}NO_3$.

On January 29, 1887, Drs. Ghy and Rondeau, of Paris, reported that one drop of a one per cent. solution instilled in the eye produced paralysis of the accommodation which lasted five days. It also produced mydriasis. The results were confirmed by Drs. Tweedy and Collins, of London. Mydriasis is produced in from five to ten minutes. The dilatation of the pupil is much more energetic than that caused by atropine, duboisine, or homatropine in the same doses. At the Congrès d'Ophthalmologique M. Trousseau said that he had used the drug two hundred and ten times without accident.

Hyoscine is a useful sedative in insomnia and motor excitation. It is given in doses of gr. $\frac{1}{100}$ to gr. $\frac{1}{120}$. A great deal was said about homotropine some years ago, but it does not seem to have held its own against other mydriatics. Its principle advantage is that its action is comparatively brief, disappearing in five or six hours. But this fugacious action is not always desirable, hence its field of usefulness is limited.

THE QUESTION OF RAG-DISINFECTION AGAIN.

Dr. Charles F. Withington has made a most exhaustive study of the above subject and his results ought to settle, for the present, the discussions which have been raised regarding rag-importation and disinfection. His conclusions are:

1. Small-pox has been transmitted through the medium of rags in a certain number of cases, small in proportion to the whole number of persons who handle rags, but absolutely numerous enough to show that unvaccinated workers in rags are exposed to an actual, if not imminent, danger of infection from this source.

2. The source of this infection is more frequently domestic than foreign rags, though the disease has been caused by the latter. This possibility of infection through imported rags accords with what is known of the tenacity of life of the variolous poison.

3. Among the rarer means whereby cholera is transmitted are textile fabrics infected with choleraic discharges. There is evidence that clothing from cholera patients, and possibly clothing merely packed in an infected locality, has, when transported to a distance and there unpacked, caused the disease in those who have handled it, thus starting a fresh cholera focus. A proper distinction exists between clothing, on the one hand, recently removed from the body and again not long after to be put on to the body; and rags, on the other hand, which, if transported to this country, are certain to have undergone a carefully discriminative sorting and drying, and to have spent a considerable time in warehouse and on shipboard.

4. The statement that cholera has been transmitted by paper rags rests upon a solitary case, of which the details are not complete, and on the reliability of which some of the highest authorities on cholera have cast doubt. If the case be accepted, it is one of infection by *domestic* rags, carried only fifty miles from their place of collection.

5. An epidemic infection known as "rag-sorters' disease" appears to have broken out on three or four occasions in European paper-mills. It was probably, though not certainly, the disease called anthrax.

6. Authenticated instances are not to be found in which the other infectious diseases—typhus and typhoid fevers, scarlet fever, measles, and diphtheria—have been transmitted through rags.

He further concludes that rag-sorters as a class are no less healthy than other persons engaged in in door manual occupations. It is, he thinks, a reasonable precaution to prohibit the importation of rags from epidemically infected localities. Workmen in paper-mills ought to be vaccinated. There should be a carefully arranged system of ventilation in the mills, and attention should be paid to domestic rags as a source of infection quite as much as to the imported article.

The Mississippi Valley Medical Association held a successful meeting at Crab Orchard Springs, Ky., July 13th, 14th, and 15th. Dr. Dudley S. Reynolds was elected President. The following interesting speech of welcome was made by Manager L. J. Frazer: "Gentlemen, it has been my fortune to see several distinguished bodies of men, among others the French Chamber of Deputies, the British Parliament, and the American Congress, but the most distinguished assembly I ever attended was the World's Medical Congress, in London, in 1881. For that pleasure I am indebted to a gentleman now present, Dr. Dudley S. Reynolds. To him, and to you all, I say welcome to Crab Orchard Springs, and may your stay be as agreeable to you as your deliberations are, and should be, beneficial to the world."

A Reporter with a sense of humor and the eternal verities made the following note: "One good effect of the gathering of physicians is seen in the rapid improvement of Miss Fanny Lyon, who was yesterday injured while horseback riding. She was sufficiently recovered this evening to receive and cheerfully entertain a number of friends."

News of the Week.

Cholera has appeared at Palermo.

Yellow Fever at Key West.—Up to July 14th there have been one hundred and ten cases and thirty deaths.

Jubilees are decidedly in vogue just now. Professor Gruber, of St. Petersburg; Professor Külliker, of Würzburg; and Professor Carl Vogt have all recently celebrated the fortieth year of their teaching.

Dr. Frederick L. Fischer, of this city, died on July 24th. He was born at Heilbronn, Würtemberg, May 1, 1817, and was graduated at Tubingen University in 1842. He was implicated in the German revolution of 1848, and in 1852 came to this city, where he has since remained as a practising physician.

A Venerable Anatomist.—On April 30th, at 11 A.M., the Anatomical Theatre of the Imperial Medico-Chirurgical Academy of St. Petersburg was the scene of a lively and noteworthy gathering of physicians, surgeons, students, and deputies from numerous learned societies, lay and medical, from every part of Russia, to congratulate Professor Wenzel Gruber upon his having held the professorship of practical anatomy for no less a period than twoscore years. During that time Dr. Gruber, besides having instructed, examined, and passed eight thousand medical students in practical anatomy, has himself dissected, or superintended the dissection of, upward of thirty thousand bodies.

Trouble among Washington Physicians.—The daily papers give publicity to the following: Last spring Dr. Sowers, of Washington, criticised, through the newspapers, the President's manner of living, from a medical point of view. Surgeon General Hamilton, of the Marine Hospital Service, preferred charges against Dr. Sowers before the Medical Association in Washington for unprofessional conduct. These charges were not sustained by the majority of the committee appointed to investigate Dr. Sowers' case, although a minority report was prepared convicting him of unprofessional conduct. Dr. Sowers has now filed charges with the Association against Dr. Hamilton. He states that Dr. Hamilton has violated two articles of the Association regulations in having shown to ex-Representative Hazelton the charges which he was about to prefer against Dr. Sowers last April. This was done, it is charged, with the full knowledge that Mr. Hazelton and his family were patients of Dr. Sowers, and was intended to lower him in the estimation of his patients.

Rheumatism as a Theme for Preachers.—The reputation which clergymen have gained as indorsers of quack remedies received an amusing illustration at Carson, Nev., lately. The Rev. Mr. Van D.—— sent to the local paper the notice of the subject upon which he was to preach the next Sunday. The actual title was, "Receipt for the Cure of Hoodlumism." This appeared in print as "Receipt for the Cure of Rheumatism," and it had the effect of crowding the church with people, many of whom had not attended divine worship for a quarter of a century, and a considerable number of whom were stiffened more or less with rheumatism.

Programme of the International Medical Congress.—The Chairman of the Committee of Arrangements announces the following programme:

First Day—Monday, September 5th.—The Congress will assemble at Albaugh's Opera House, at 11 A.M., and will be formally opened by the President of the United States, to be followed by a short address of welcome by the Secretary of State; address by the President of the Congress; report of Secretary-General and Chairman of Committee of Arrangements. Adjourn at 1.30 P.M. From 3 to 6 P.M., meeting of the Sections at their respective halls. Evening *conversazione* at U. S. Pension Hall from 8 to 11 P.M.

Second Day—Tuesday, September 6th.—Meeting at 10 A.M. at Albaugh's Opera House. General addresses by Drs. Flint and Semmola. Sections will meet at 11 A.M., and adjourn at the same hour with Congress at 1 P.M. In the afternoon the Sections will meet from 3 to 6 P.M. In the evening it is expected that a reception will be given by the President of the United States, and the Corcoran Art Gallery will be thrown open to the members and their families.

Third Day—Wednesday, September 7th.—The Congress will meet at 10 A.M. General addresses until 1 P.M. The Sections will meet as usual at 11 A.M., and adjourn at 1 P.M. Afternoon meeting of the Sections from 3 to 6 P.M. Evening reception to the members and their families by the citizens of Washington.

Fourth Day—Thursday, September 8th.—General meeting at 10 A.M. Addresses, if not previously delivered. Meeting of the Sections at 11 A.M.; adjourn at 1 P.M. Afternoon, Sections meet from 3 to 6 P.M. General reception buffet banquet at U. S. Pension Hall from 8 to 11 P.M.

Fifth Day—Friday, September 9th.—General meeting at 10 A.M. Transaction of business affairs of Congress. Meeting of Sections at 11 A.M., and adjourn at 1 P.M. Afternoon, Sections meet from 3 to 6 P.M.

Sixth Day—Saturday, September 10th.—General meeting at 10 A.M. Adjourn at 11 for visit to Mount Vernon.

On Sunday or Monday, the day not yet determined upon, an excursion train will leave Washington with the foreign members and their families for Niagara Falls, under the escort of a part of the Committee of Arrangements, selecting the route which will afford our foreign brethren an opportunity to see some of the most interesting and thrifty portions of our country, as well as very beautiful scenery.

In completing the details of this programme it may be necessary to make some slight modifications.

Medicine in New Haven.—There were 100 doctors in New Haven, Conn., eight years ago, of whom 11 were homœopaths. Now there are 129, with 18 homœopaths.

Professor Virchow's Report on the third piece of tissue removed from the Crown Prince's throat ends as follows: "The tissue did not in any part exhibit an alveolar structure, nor any epithelial deposit or ingrowth. It consisted of delicate connective tissue, which increased toward the surface, but not in the other direction, and in part contained proliferating elements. Nowhere did this proliferation attain the character of independent centres of growth. The excised portion has, therefore, to a greater extent than that removed at the last operation, the character of a hard compound wart growing on a moderately irritated and thickened surface, and its base does not favor in the slightest the opinion that it is a new growth invading the tissues."

The State Board of Health of West Virginia is suffering, says the *Wheeling Daily Intelligencer*, from a governor not in sympathy with its work and purpose. He has recently appointed as a member a physician declared by twenty-nine physicians of Wheeling and by the State Society to be ineligible.

Can Doctors Practise Dentistry?—A case involving this point recently came up in this city, and was decided in the affirmative. A Dr. Bradford was charged with illegally practising dentistry. He showed that he was a legal physician, and the complaint was dismissed.

Bequest to a Medical School.—A valuable library, together with the sum of 15,000 francs, has just been bequeathed to the Medical School of Montpellier by M. Bouisson, who desires that the monetary legacy shall be employed in erecting a suitable building for the reception of the volumes and for the expenses of printing a catalogue. In addition to all this, M. Bouisson has left 100,000 francs to found five annual prizes to be called by his name.

The late Dr. J. S. Jewell.—The announcement made in the general session of the A. M. A. at the last meeting in Chicago by Dr. N. S. Davis, to the effect that the books and instruments of the eminent scientist, Dr. J. S. Jewell (recently deceased), of Chicago, were on sale at a neighboring book-store, and the purchase on the part of members would be of great aid to his wife and children, was a sad commentary upon the error of a slavish and absorbing devotion to the scientific part of the medical profession at the expense of money, family, health, and life itself. A man's first duty is to his family; this being the case the query may well be made as to whether the physician, the soldier, or the clergyman should be permitted to marry.—*Weekly Medical Review.*

Treatment of Toothache Due to Dental Caries.—Dr. Popoff, writing in the *Russkaya Meditsina*, states that he has succeeded in relieving toothache caused by caries of the teeth by making the patient rinse the mouth every half-hour with a dessert-spoonful of a twenty per cent. solution of permanganate of potash, taking care to hold the liquid in the mouth for some minutes.

Curing Cancer Homœopathically.—An ingenious homœopath, Dr. C. F. Ring, has had prepared triturations of the proximate principles that go to make up carcinomata, and suggests for epitheliomata—keratin, leucin, tyrosin. For scirrhus—tyrosin, kreatin, karnin, sarcosin. For encephaloid—kreatin, kreatinin, hæmoglobin. For melanotic cancer—*melanin*, kreatin, hæmin, hæmatin. For colloid cancer—leucin, sarkin. For osteoid cancer—leucin, tyrosin. For innocent tumors—the proteids and the carbo-hydrates. For semi-malignant growths—both the crystallizable and non-crystallizable proximate principles. Dr. Ring does not seem to have tried his remedies, or perhaps he would not have written so much about them.

Reports of Societies.

AMERICAN OTOLOGICAL SOCIETY.

Twentieth Annual Meeting, held at the Pequot House, New London, Conn., on July 19, 1887.

The Society was called to order by the President, Dr. J. S. Prout, of Brooklyn.

In the absence of the Secretary, Dr. E. E. Holt, of Portland, was elected Secretary *pro tem.* Resolutions expressing regret at the absence of the Secretary, Dr. J. J. B. Vermyne, who was prevented by ill-health from being present, were adopted.

Dr. John Green, Dr. J. A. Andrews, and Dr. J. A. Lippincott were appointed as a Nominating and Business Committee.

The report of the Committee of Conference with reference to the formation of a Congress of American Physicians and Surgeons was adopted.

The naming of the representative and alternate to the Executive Committee of the Congress was left to the Nominating Committee.

THE EXAMINATION OF THE POWER OF HEARING, AND HOW TO RECORD ITS RESULTS,

was the title of a paper read by Dr. H. Knapp, of New York.

This was the report of a committee consisting of Drs. H. Knapp, J. S. Prout, and D. B. St. John Roosa. The tests for hearing described were the watch, the voice, Politzer's acumeter, and the tuning-fork. The watch is one of the best means of testing the hearing. A low-ticking watch is of service in indicating the lowest degree of hardness of hearing in those cases where the patient has not become aware of the defect. This is, however, not sufficient to measure the higher degrees of deafness. In these cases a loud-ticking watch or Politzer's acumeter must supply its place. Each of these instruments must be tested by the physician in his office on a number of normal ears, in order that he may obtain a standard. It is a fact that in persons over fifty-five years of age a low-ticking watch may not be heard when placed over the temporal or mastoid bone if the ear is closed, but will be heard if the ear is open.

With reference to the voice as tests for hearing, the whispered voice, the voice of ordinary conversation, and the loud voice are used. Each observer must test his own voice by the acuteness of hearing of normal persons between twenty and forty-eight years of age. The state of the room as to noise and quiet should always be considered; the tuning-fork over all parts of the skull is heard louder and longer when the ear is closed than when it is open. All tuning-forks are heard longer by air-conduction than by bone-conduction. Low tuning-forks are heard louder, but not longer, by bone-conduction than by air-conduction. Departure from these conditions indicate disease.

Dr. Samuel Sexton, of New York, said that it seemed to him that sufficient importance had not been given to the varying conditions of the patients themselves. In cases of chronic catarrhal inflammation of the middle ear, and also in acute forms of inflammation, there are constantly varying changes in the tension of the drum and in the transmitting mechanism. In these cases the acuteness of hearing changes from hour to hour or day to day. He had noticed that in the morning, when the perceptive faculties are active, a patient will hear better than he will later in the day. It is also well known that the vapor-tension of the air, as well as the temperature, has something to do with the transmission of sound. The hearing is better in cold weather than in hot.

Dr. D. B. St. John Roosa, of New York, was not inclined to lay such stress upon the variations in hearing from hour to hour in cases of chronic inflammation of the middle ear. These variations do occur in cases of disease of the middle ear, but they are more marked in disease of the internal ear. In cases of a nervous deafness, the condition of nervous exhaustion has much to do with the capacity for hearing.

Dr. Samuel Theobald, of Baltimore, had noted in certain cases that when he had placed the tuning-fork on the vertex the patient would hear it louder in one ear, say the right. Then striking the fork again and placing it upon the forehead it will be heard best in the left ear. This had given him less confidence in the tuning-fork as a differential test between middle-ear and labyrinthian troubles.

Dr. H. Knapp, of New York, said that for practical purposes we must test the hearing as accurately and with as little loss of time as possible. In certain cases of chronic catarrah no change could be gotten in the hearing power by any test. In these cases he thought that nothing is to be looked for from treatment. Where, however, by changes of weather or changes in the patient's condition, there is a change in the hearing-power we know that there is something to improve. We get not only an estimation of the condition, but we also get a foundation for prognosis and an indication for treatment.

Dr. Charles H. Burnett, of Philadelphia, gave an account of

THE SUCCESSFUL REMOVAL OF AN EXOSTOSIS FROM THE EXTERNAL AUDITORY CANAL BY BONE-FORCEPS AND CHISEL.

The patient was a physician, about thirty years of age, in whose right ear the exostosis had been growing for fifteen years, and within the past year it had entirely occluded the meatus and caused deafness. The growth was about one centimetre in diameter, pediculated, and attached to the anterior wall of the meatus just within the outer edge of the tympanic bone. Its outer surface was covered with thick and rather insensible skin. After a hypodermic injection into the concha of fifteen minims of a five-per-cent. solution of hydrochlorate of cocaine, the outer surface of the exostosis was seized by specially devised bone-forceps and a piece of the bone-tumor cut off. About one-half of the growth was thus removed in successive pieces. As the blades of the forceps could not enter farther into the meatus and get hold of the remnant of the exostosis, a small chisel a few millimetres in width was placed against the attachment and a blow from a hammer on the chisel knocked off the remainder of the growth *en masse*. The operation caused very little pain or bleeding. The fundus of the canal and the membrana tympani were covered with a glove finger cast of epithelium. This was removed and the hearing found to be normal. The ear was dressed with a little iodoform and stopped with cotton. There was no reaction, and the cut surface of bone on the wall of the meatus at the point of attachment of the exostosis was entirely covered with skin in two or three days. Usually, drills impelled by the dental lathe have been used to open the lumen of the canal occluded by exostosis. The novelty in this case consisted in the use of bone-forceps, devised by the author, to remove the growth as far as possible, and then the use of hammer and chisel to complete the opening.

Dr. H. Knapp, of New York, said that to attack these exostoses at the apex with the chisel, where they consist of ivory-bone, is most difficult. The most efficient way, in my experience, is to attack them at the base, cutting through healthy. Here the bone may be much softer. In the after-treatment cleanliness and antiseptic precautions are of the utmost importance.

Dr. J. A. Andrews, of New York, said that where these osteomata are situated in the orbit much serious injury may be inflicted upon the brain by the use of the chisel. It would be much easier to fracture the plate of bone lying against the brain in osteoma of the frontal sinus by attacking the tumor itself than by attacking the bony surroundings of the growth.

Dr. D. B. St. John Roosa, of New York, read a paper on

THE DIFFERENTIAL DIAGNOSIS BETWEEN AFFECTIONS OF THE MIDDLE EAR AND THOSE OF THE LABYRINTH.

There has been some difference of opinion as to our ability to differentiate between affections of the middle ear and those of the labyrinth. Many cases usually classed under affections of the tympanum should be placed among diseases of the cochlea, or of the acoustic nerve. The records of seven recent cases were given in detail. These cases were nearly all in the middle period of life, when its cares and troubles are most pronounced. Such patients often exhibit symptoms of nervous exhaustion. These cases may be benefited by the administration of strychnia, arsenic, and quinine; proper hygiene should be employed. The universal use of the watch as a test of hearing occasionally leads to false conclusions on the part of the general practitioner who discovers loss of hearing by testing with the watch alone. When used alone, I regard the watch as insufficient; when both the watch and the voice are heard badly, there is cause for anxiety. Many persons have lesions which cause them to hear the watch and certain other tones badly, but who can hear the voice well. In the opinion of the author, those persons who hear conversation better than the watch, who hear better in a quiet room than where there is noise, and who hear the tuning-fork better through the air than through the bone, suffer from an affection of the labyrinth or nerve, and not from disease of the tympanum, although the latter may be engrafted upon the previous affection. The general adoption of this view would save a good deal of local treatment of the naso-pharynx and tympanum, and greatly simplify and improve our therapeutics. As far as the aural condition is concerned, I regard these cases as incurable. I think we can assure these patients that if the general health be looked after carefully, they will never hear so badly but that they can hear in a quiet place. This has a good moral effect—it makes the patient happier, and enables us to dispense with much useless treatment.

Dr. E. E. Holt, of Portland: For several years I have performed experiments with the tuning-fork, but I have not been able to reach the same conclusions as those presented by Dr. Roosa. You may find quite a degree of deafness and still the tuning-fork will be heard much longer by air-conduction than by the bone. I have seen many cases where bone-conduction would be longer than air-conduction, and where by treatment the air-conduction would become longer. It is difficult to test the hearing properly with the watch unless it is made with a stop.

Dr. D. B. St. John Roosa, of New York, made some

REMARKS UPON A CASE OF CEREBRAL ABSCESS.

The patient, a boy eleven years of age, came under observation, May 4, 1887, with a painful swelling over the right ear. It was said that the boy had had some trouble with the ear two years before, but that there had been no discharge. For three months he had had tinnitus aurium and vertigo. One week before he was seen he had had pain in the ear, then this swelling appeared. Bone-conduction with the tuning-fork was better than aërial conduction. The hearing-power of the left ear was normal. Immediately above and in front of the auricle there was a swelling about the size of a walnut. This presented fluctuation. There was a history that previous to admission to the hospital the treatment had consisted in the use of injections and the insufflation of powders. The auditory canal was filled with a white substance, which was supposed to be the powder that had been employed. The day after admission the patient was etherized and the abscess opened, with the removal of half an ounce of laudable pus. No fistula was discovered. The patient did well for nine days. Nausea and vomiting then set in, and the temperature went up to 104°. The patient sank into a condition of coma and died on the tenth day after admission. At the autopsy there was found a cerebral abscess one and one, half inch in diameter, situated in the temporo-sphenoidal lobe, half an inch from the surface of the brain. This was lined with thick membrane. The membrana tympani was perforated, and the upper wall of the canal was necrotic. At the junction of the mastoid and squamous bones there was a spot of necrosis half an inch in diameter. The canal and mastoid cells were filled with caseous material.

Dr. Roosa also reported the history of

A CASE OF SUPPURATION OF THE TYMPANUM OCCURRING IN A PATIENT WITH BRIGHT'S DISEASE.

The patient, a woman forty-two years of age, was seen on April 11, 1887. There was intense pain, referred to the left ear, which had existed since the day before. The hearing was much impaired, as the result of a chronic non-suppurative inflammation of the middle ear. The bone-conduction was better than the aërial. There was a watery discharge from the left auditory canal. Examination of the urine revealed the presence of Bright's disease, and the patient died some days later from œdema of the lungs. The point which the author made was that, although this patient complained a good deal of the mastoid process, it was determined that there was no lesion requiring operation because of the absence of the characteristic symptom of tenderness at the apex. The case was regarded as one of tympanic trouble. The post-mortem proved that there was no trouble with the mastoid, but acute suppuration of the tympanum, occurring in a patient with chronic non-suppurative inflammation. The patient died from the Bright's disease.

Dr. W. H. Carmalt, of New Haven: The author speaks of tenderness of the mastoid as though it were an almost infallible sign of suppuration in the mastoid cells. I would ask if we should expect to find this sign always?

Dr. Roosa: I think that this is a very strong test, although by no means infallible.

Dr. Emil Gruening, of New York: I have this winter seen a number of cases of abscess. In two months I saw seven cases. In children I open the abscess and invariably open the mastoid cells. I do this especially where the abscess has been preceded by otitis media purulenta. In four of the seven cases the mastoid cells were filled with pus. In this way through drainage was established and all the patients recovered. I saw three cases of otitis media purulenta treated by insufflation of powder, leading to retention of secretions and death. All died of meningitis.

Dr. Lucien Howe, of Buffalo: This calls to mind one which I had in a child where there was a history of recurring attacks of ear trouble with discharge. It was stated that good results had been obtained by the use of alum and boric acid. This was continued and the patient began to develop the typical signs of mastoid trouble. I etherized the child and removed the accumulation in the outer ear; all the symptoms then subsided.

Dr. W. H. Carmalt, of New Haven: The fact that the cerebral abscess was surrounded by a thick membrane does not prove that it was of long duration. In a recent case of cerebral abscess, resulting from an injury over the parietal bone, I attempted to reach the abscess by trephining, and passed my knife two and a half inches in the direction where I supposed the abscess to be, but got no pus. The man died, and I found an abscess in about the position I had passed the knife, but the wall was so thick that the pressure of the knife had squeezed the pus into the lateral ventricles and death had been the result. In this case the operation was performed within two months of original injury.

Dr. O. D. Pomeroy, of New York, presented a paper entitled

DESQUAMATIVE INFLAMMATION OF THE MIDDLE EAR, WITH REMARKS,

which was read by title and referred to the Publication Committee.

Dr. E. E. Holt, of Portland, exhibited

AN EFFICIENT POWDER-BLOWER, WITH REMARKS ON THE USE OF POWDERS IN THE TREATMENT OF DISEASES OF THE EAR.

The powder-blower consists of six or eight inches of small glass tubing, to which is attached about fifteen inches of rubber tubing. The glass tube is plunged into the powder until a sufficient amount is introduced into it. The powder is gently drawn into the proximal end of the glass tube. The distal extremity is then placed in the speculum and the powder blown into the ear. By drawing the powder from the distal end before blowing it, it is carried *en masse* to the desired point and applied evenly to all parts. The instrument can be used with great facility.

After trying various powders, boric acid has been found the most efficient in the largest number of cases. One of the first cases in which the author had used this powder was one in which treatment for over two years had failed to cure a suppurative otitis media. Upon the application of the powdered boric acid the discharge ceased and has not returned—a period of five years. Cleanliness before using the powder is essential. A comparison of cases of chronic suppurative otitis media treated with boric acid with those treated without this agent led to the conclusion that while the discharge from the ear ceases much earlier when the powder is used, yet perforations in the drum-head heal less frequently.

Dr. Samuel Theobald, of Baltimore, exhibited a powder-blower similar to that of Dr. Holt, with the exception that the glass tube was substituted by a piece of goose-quill, and that the rubber tube was furnished with a mouth-piece consisting of a quill. The powder is introduced into the quill and, by shaking, brought to the proximal extremity of the tube, the object being that it shall be thrown into the ear in the form of a cloud.

Dr. William W. Seeley, of Cincinnati, said that he had never seen any benefit from blowing powder into the ear. He had only seen good results where the powder is packed into the canal. He, however, now rarely uses the powder in any way. In these cases of suppuration there are three points to be observed—the Eustachian tube should be kept open, the naso-pharynx should be treated as in any other case of inflammation of the middle ear, and the ear should be kept clean by the use of cotton tubes.

Dr. D. B. St. John Roosa, of NewYork, remarked that he found the syringe the best means of cleaning the ear. He considered powders inferior to other methods of treatment.

Dr. B. Alexander Randall, of Philadelphia, stated that in treating a number of cases of purulent discharge which had continued from five to fifteen years, and in which the discharge had been pretty continuous and fetid, he had cleansed the canal and used boric acid, at first blowing it in lightly, and finally filling the canal pretty full without packing. Within a few days the powder is dissolved, and the discharge is usually diminished in quantity and the odor is lost. In eight out of every ten cases that had been his experience. He had never seen any bad results.

Dr. H. Knapp, of New York, in acute cases of otorrhœa used boracic acid as an antiseptic and cleansing powder. The patient is directed to cleanse the ear with the syringe three times a day. The powder is then introduced by means of a spoon until the canal is loosely filled. If the powder becomes moist the patient is directed to syringe the ear and renew the application. The majority of acute cases do not require any other treatment. In chronic cases he removes any polypoid growths or any carious bone that may be present, and then uses alcohol in fifty or sixty per cent. strength, or absolute with sulpho-carbolate of zinc, and changes that with nitrate of silver. He continues this treatment until there is no discharge, and directs the patient to do nothing beyond using a light cotton plug to filter the air. In one case he makes an exception, and that is when a perforation of moderate size has perfectly clear edges and remains in the same condition for weeks or months. Here he pastes a small piece of sized paper over the perforation. In many cases the hearing is improved, and it seems to stimulate the healing of the perforation.

Dr. C. R. Agnew, of New York, said that in using fluid applications in the treatment of these cases he had employed a procedure which must be new to some of the members. After cleaning the ear in which he wants to diffuse a fluid application as much as possible, he turns that ear uppermost and fills the external canal with the solution. Then he inserts the nozzle of the Politzer apparatus into the external canal and makes pressure, diffusing the liquid to all parts of the ear and making it appear, in some cases, in the pharynx. This sometimes may be of value.

Dr. Samuel Theobald thought that both powders and solutions may be used with advantage. He had never seen any direct harm follow the use of boracic acid. In cases of suppuration, with a small or moderate sized perforation, he had seen it dry up the discharge and leave the perforation larger than before its use. In such cases he prefers solutions. In acute cases his practice is to always use solutions. He had used a fifteen-grain solution with satisfaction. Where the drum-membrane is practically gone, with a granular condition of the mucous membrane, the use of boracic-acid powder is indicated. He had never found it necessary to pack the canal. One puff of the powder-blower fills the canal sufficiently full.

Afternoon Session.

The discussion on the use of powders in the treatment of inflammation of the ear was continued.

Dr. H. Knapp, of New York, said that in acute suppurative otitis, which is certainly of bacterial origin, he used boric acid largely on account of its drying properties. Suppuration, fermentation, and decomposition do not take place where a part is kept dry. As soon as the boric acid becomes moist he had it removed. For acute cases he knew nothing better than this method of treatment.

Dr. Emil Gruening, of New York, with reference to three cases which he had already mentioned, said that in these cases he attributed the fatal result to the use of powder, which was boracic acid. The first case, that of a girl nineteen years of age, had otitis as a result of the use of the nasal douche. In a few days she began to suffer with headache, dizziness, and intense tenderness on one side of the head and slight puffiness in the region of the mastoid. He saw the patient after she had become comatose, and found the tympanic membrane bulging and injected. There was a slight tit-like projection, and in this there was an opening filled with powder. He made an opening in the membrane and cleaned it out carefully, and advised the family physician to open the mastoid. He did so, and found the mastoid cells filled with pus. The patient recovered consciousness, but died the next day from heart-failure. The second case was that of a lady, seventy years of age, who had otitis media with perforation. A powder was applied, and a few hours later she began to suffer with intense headache. Symptoms of meningitis appeared, and the speaker was called in. He found a small opening in the membrane occluded with powder. A free opening was

made, but the patient died of meningitis. The third case was that of a child with long-standing otitis media and destruction of both membranes. This is the only case in which the powder had been packed. After the ears had been packed the child had repeated chills. I was called in and removed the plugs, which were hard, concrete masses and were taken away with difficulty. In spite of the removal of the powder the child died, with all the symptoms of pyæmia.

Dr. D. B. St. John Roosa, of New York, thought that in a large percentage of cases acute inflammation of the middle ear is a self-limited affection. He tries to secure cleanliness and then dries the parts. He did not use dryness as a means of destroying the germs or preventing them from acting, for he does not believe in the germ theory of disease. In a large proportion of the acute cases the only treatment required is irrigation with warm water *pro re nata* and drying afterward. He believes that the pus has a chemical quality, apart from the presence of germs, which renders it corrosive.

Dr. Samuel Sexton, of New York, said that, in the cases referred to by Dr. Gruening, where there is a nipple-like formation there is little discharge from the atrium. In these cases he makes an early and free opening, and in this way has avoided many of the consequences which are apt to follow in these cases. The opening is made through the membrana flaccida into the attic, and through the integument of the upper wall, which usually becomes tumefied.

Dr. Samuel Theobald, of Baltimore, did not think that the good effects of boric acid are due to its drying qualities alone. Some of his most brilliant results have been with the solution of boric acid.

Dr. J. A. Lippincott, of Pittsburg, counted boric acid a most valuable agent. There are, however, certain cases in which, as a result of idiosyncrasy on the part of the patient, the powder acts as an irritant. In the cases reported by Dr. Gruening the fatal results are to be attributed to its improper use. It seemed to him that the dangers of boric acid can be avoided by applying it in the form of a loose powder

Dr. Charles H. Burnett, of Philadelphia, read a paper detailing

AN EXAMINATION OF FIFTEEN DEAF-MUTES BY MEANS OF J. A. MALONEY'S OTOPHONE.

The cases examined were pupils in the Pennsylvania Institution for the Deaf and Dumb, Philadelphia, and were between the ages of twelve and twenty-one years of age. The cases were divided into three classes: 1, Congenital cases; 2, those losing their hearing between the ages of one and five years; 3, cases of profound hardness of hearing, but who still hear a little and can talk, so-called semi-mutes.

The method of procedure was as follows: Five vowels were written and pointed out at the time of their repetition three times in succession, through the otophone, by Mr. Maloney. The pupil was then told to indicate which vowel was spoken, when Mr. Maloney made another repetition, care being taken to mix about in the tests. The words *Philadelphia*, *Mississippi*, *Burlington*, *Missouri*, *boy*, *baby*, *papa*, and *mama* were also used as tests, as well as the consonant *B*.

Hearing was excited in every instance; but fourteen of the fifteen cases gave ample evidence of hearing by their successful indications with the pointer as the different tests were repeated in their ears. It was noted that the results were not as good with the acquired cases as in the so-called congenital cases of deafness. This may be due to the fact that the process productive of the acquired form is more violent, involving the internal ear, as in spotted fever, than in congenital cases, which generally give evidence of being simply catarrhal in their origin, and affect the middle ear but not the internal auditory organ. In the case of semi-mutes, the results were especially satisfactory, as they heard nearly everything said to them, and returned intelligent answers to the questions. In such cases, both the remaining hearing and the articulation could, in all probability, be improved by the systematic employment of such an instrument as the otophone as a means of instruction, the best results being obtainable where the instruction is begun early in life.

A paper with the same title was presented by Dr. F. B. Loring, of Washington. In the absence of the author the paper was read by title.

Dr. William W. Seely, of Cincinnati, asked whether the use of this instrument was recommended simply as a help to hearing, or as a therapeutic measure.

Dr. C. H. Burnett, of Philadelphia, said that the instrument seems to be an immediate help and is also a valuable therapeutic measure. In the case of an extremely deaf person who was unable to hear a loud voice when the words were spoken close to the ear, and who with an ordinary ear-trumpet could hear slightly, with this instrument he could hear fairly well from the first. After exercising for fifteen minutes, he was able to hear with closed eyes the unaided voice, the words being spoken a foot from the ear.

Drs. H. L. Morse, of Boston, and B. Alexander Randall presented a series of photographic illustrations of the anatomy of the human ear.

Dr. Samuel Sexton, of New York, read a paper entitled

EXCISION OF THE OSSICLES OF THE DRUM OF THE EAR FOR CHRONIC PURULENT INFLAMMATION OF THE MIDDLE-EAR TRACT.

Since bringing this subject to the attention of the Society, one year ago, the writer has continued the practice with satisfactory results and presented some further observations, based upon the records of 19 operations. Of these 19 operations, 13 were on females and 6 on males. Seven cases were between five and twelve years of age, 8 were between thirteen and twenty years of age, and 4 were between twenty-three and forty years of age. The left ear was affected in 11 cases, the right in 8. In 2 cases both ears were the seat of suppurative inflammation, and in 1 there had been a mastoid abscess. In the majority of the cases there had been a history of recurrent aural catarrh for a long time, attended with pain in the ear. There was much deafness and distressing acoustic phenomena, as autophonia, and the like. The discharge was usually offensive. The general health of most of the patients was fair.

In all cases the drum-head was greatly impaired, the membrana vibrans being usually almost entirely gone; in most of the cases the membrana flaccida alone remained, perhaps with some portion of the membranum vibrans attached. Where any of the latter remained, it was liable to be found connected by bands with the inner wall of the tympanum. Sometimes a sinus of greater or less size opened through these diseased structures into the attic. The membrana flaccida, together with the membranous and ligamentous attachment of the ossicles, generally held the latter in place, even after the most extensive suppuration had long existed. Under these circumstances, drainage was extremely likly to be interfered with. The manubrium and cicatricial structures depending from the auditory plate were frequently found adherent to the inner wall of the tympanum, while the attic and antrum were lined with much thickened mucous membrane.

Some portion of the middle-ear tract was found to present more or less carious bony surface. In some instances the ossicles themselves were carious or anchylosed. In several of the cases the malleus handle was adherent to the inner wall of the drum. In some, only a necrosed stump remained. In some, the malleus and incus were adherent to each other. The incus was less liable to caries. The stapes cannot be so well examined as the other bones, since it is never removed. In some of the cases the operation was not resorted to until months or

years after ordinary methods of treatment had been resorted to without success.

Without going into all the details of the operation, the author said that experience had shown that it may be performed much more rapidly than was at first supposed. The first operations required an hour, the later ones not more than fifteen minutes. To the protracted operation he attributed some disagreeable symptoms, such as nausea, which had not been presented by the later cases.

The remaining fragments of the drum-head are everywhere detached from the tympanic ring with a slender, trowel-shaped knife. The malleus is then freed from its attachments, including the tensor tympani muscle, by one or more sweeps of the knife. After all blood is removed the long process of the incus is separated from the stapes, if it be connected with that bone. The malleus handle is separated from the inner wall of the canal, if it has been attached. The malleus handle is seized with stout forceps as high as possible and gradually detached and brought away. The removal of the incus is more difficult, since its long process is liable to be swept from view. With a little patience, however, the bone may be soon found, and its removal is then a simple matter. When lying in the attic, the scraper may be of service in bringing it down. In most instances he no longer divides the chorda tympani. In some cases, where the ossicles were very adherent, considerable force was necessary to detach them, and in one instance this was impossible.

After the operation the drum should be carefully dried with cotton, and ten drops of a four per cent. solution of cocaine may be instilled. This is usually unnecessary. Usually very little or no reaction follows the operation. In females it is important to defer operation until a little time after the menstrual period.

In the 19 cases both malleus and incus were removed in 10. In 1 the body of the incus alone was removed. In 6 cases the malleus only was excised.

When possible, it is well to clear the drum of granulation-tissue by treatment before the operation, since less hemorrhage will then be encountered. The duration of treatment after the operation was, in 5 cases, one month; in 2, two months; in 2, three months; in 1, six months; and of the other 9 cases, 3 were unimproved, 1 failed to continue treatment, and 5 are yet under observation. Many of these were dispensary patients under bad physical conditions. A marked improvement in hearing occurred in nearly all cases. In the cases noted as cured, it was restored to from seventy-five to one hundred per cent. of the normal as far as testing with voice was concerned.

This marked improvement in hearing was unexpected, and gave rise to the conjecture that we may recommend the operation for deafness alone in many cases where the drum is obstructed by the results of chronic purulent inflammation, although all discharge may have ceased.

It might be expected that the taste might be affected by injury to the chorda tympani nerve. In a few this was the case for a short time. Recovery, however, always took place. Reproduction of the drum-head never took place. Among the results of the operation may be mentioned the prevention of recurrent accumulations of purulent matter in the attic and antrum. The general health was nearly always improved. In two phthisical cases the cough was lessened in one and ceased in the other, while both gained much in weight. In children the effect on health was most marked.

The operation is performed with the patient upon the back and under ether narcosis. The electric light is almost essential. Magnifying lenses introduced into the speculum are of service in making preliminary examinations. The after-treatment consists in keeping down granulation-tissue and aiding in the transformation of the mucous lining into a dermoid condition. A meddlesome plan of treatment is undesirable. Where a large secreting tract exists a cure is sometimes almost impracticable. Alcohol has not been found useful in treating granulation-tissue. Salicylic acid and boric acid have done good in a few cases. The peroxide of hydrogen has its use in certain cases. The persistence of discharge after operation may be expected in catarrhal and run-down subjects, especially where caries of the bone exists.

The specimens removed in these nineteen cases were presented.

Evening Session.

"A case of Rapid and Almost Total Loss of Hearing in a Child Seven Years of Age; Inherited Syphilis apparently the Cause; Marked Improvement following the Use of Iodide of Potassium," by Dr. A. H. Buck, of New York, was read by title.

Dr. Samuel Theobald, of Baltimore, reported

A CASE OF SYPHILITIC DISEASE OF THE LABYRINTH,

exhibiting remarkable variations in the degree of deafness.

The patient was a man about thirty-four years of age, the subject of inherited syphilis. In one ear the deafness was nearly complete, and in this ear there was but little variation. In the other ear frequent and sudden relapses occurred after the hearing on several occasions had been brought up almost to the normal standard. Within twenty-four hours the hearing would fall from the ability to distinguish words in a whisper at twenty inches, to a degree of deafness which would require the same words to be spoken in a loud voice. Iodide of potassium was given with but little effect, but decided benefit resulted from the administration of bichloride of mercury in combination with muriate of ammonia.

Executive Session.

The following were elected to membership: Drs. J. C. Lundy, of Detroit; Wm. H. Hotchkiss, of New Haven; S. D. Risley, of Philadelphia; and David DeBeck, of Cincinnati.

OFFICERS FOR ENSUING YEAR.

President—Dr. J. S. Prout, of Brooklyn.

Vice-President—Dr. George C. Harlan, of Philadelphia.

Secretary and Treasurer—Dr. J. J. B. Vermyne, New Bedford, Mass.

Representative to Executive Committee of Congress of American Physicians and Surgeons—Dr. C. R. Agnew, New York.

Alternate—Dr. Wm. H. Carmalt, of New Haven.

The next meeting of the Association will be held at the Pequot House, New London, Conn., Tuesday, July 19, 1888.

An Apparatus for the Application of Dry Heat.—Dr. G. M. Shillito, of Allegheny, Pa., sends a description of an apparatus devised by him for the continuous application of dry heat. The apparatus consists of a copper boiler, in which the steam is generated, and a flattened circular vessel of very thin brass, covered with six folds of cotton-sheeting and one of muslin on the outside. The steam is conveyed from the boiler through tubing to the hollow, disk-like vessel, which is supported on a light wire rack at any required distance from the patient's body. The steam then passes into a condensing vessel, placed on the floor near the bed, or on the bed itself. Dr. Shillito has employed the apparatus in acute pleurisy, peritonitis, and puerperal metro peritonitis, with very satisfactory results. In one instance the heat was applied constantly, the apparatus never being cool for fourteen days.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 17 to July 23, 1887.

HEGER, A., Lieutenant-Colonel and Surgeon. Assigned to duty as member of Army Retiring Board, command at Governor's Island, New York Harbor, N. Y.; *vice* Colonel Charles Sutherland, Surgeon, hereby relieved. Par. 13, S. O. 167, A. G. O., July 21, 1887.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. By par. 43, S. O. 162, A. G. O., July 15th, so much of par. 1, S. O. 156, c. s., A. G. O., as directs him to report for duty at Fort Washakie, Wyo., is revoked.

TORNEY, GEORGE H., Captain and Assistant Surgeon. By par. 42, S. O. 162, A. G. O., July 15th, so much of par. 1, S. O. 156, c. s., A. G. O., as relieves him from duty at Fort Monroe, Va., is revoked.

BARNETT, R., Captain and Assistant Surgeon. Sick leave still further extended six months, on account of sickness. S. O. 162, A. G. O., July 15, 1887.

TAYLOR, A. W., Captain and Assistant Surgeon. Now at Laramie, Wyo., is ordered for temporary duty at Fort Robinson, Neb. S. O. 162, A. G. O., July 15, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 23, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	15	5
Scarlet fever	48	8
Cerebro-spinal meningitis	3	3
Measles	29	4
Diphtheria	89	34
Small-pox	8	2
Yellow fever	0	0

ELECTRICITY IN THE TREATMENT OF TEDIOUS LABOR AND POST-PARTUM HEMORRHAGE.—Dr. Fayette reports the following case: The patient was a primipara, twenty-three years of age. Twelve days before labor came on he was engaged to attend her, and on examining her urine he found it contained a large quantity of albumen. When labor commenced the woman's face was œdematous, pulse 110. Head presented in the first position. The os uteri was at first rigid, but gave way after a dose of 30 grains of chloral-hydrate. Uterine contraction was feeble and ineffectual. After working twelve hours, a strong and rapidly interrupted current of electricity was brought to bear on the inert uterus. When the head came down on to the perineum the current was stopped. After delivery, as the uterus did not contract well, a dose of ergot was given. About an hour later the doctor was called hurriedly upstairs and found his patient flooding. He at once passed his hand into the uterus, but did not succeed in setting up contraction; he then removed the clots and injected vinegar, but still no effectual contraction took place. The injection of hot water was equally in vain. The battery was then requisitioned, and, with the positive electrode in the patient's hand and the doctor holding the negative electrode in his left hand, he grasped the flaccid uterus through the abdominal walls with his right hand; the effect was instantaneous, the uterus at once becoming powerfully contracted, and the hemorrhage ceased. After a few minutes the current was discontinued and the bleeding did not recur.

A CALCULUS IN THE BRONCHUS.—Dr. Montané recently communicated the following case to the Havana Academy of Sciences. The patient was a young lady from the United States, who, up to 1884, when she was first seen, had enjoyed good health. In that year she had an attack of pleurisy on the right side, for which parathoracentesis was performed, which removed nine hundred and thirty grammes of fluid. After this she completely recovered. In the early part of 1886 she was again seen for a persistent dry cough, which was considered to be due to pharyngitis, but which did not yield to the remedies prescribed. A painful spot was complained of at the base of the neck, a little above the left sterno-clavicular articulation. Up to May 13th there had been no elevation of temperature; for some days after this, however, there was a slight degree of fever, which was quite unaffected by quinine. The cough afterward became more spasmodic—somewhat resembling whooping-cough; some streaks of blood also appeared in the sputum. On auscultation occasional dry rhonchi were heard over the left apex, and a slight roughness in the breath-sounds; there was, moreover, a want of percussion-resonance in the left infra-clavicular region. An active counter-irritant was applied, and digitalis ordered, but no good effect was produced. On the morning of May 20th it was noticed that the respiratory sounds over the left apex had become weaker, and in the afternoon the whole of the left lung was almost impermeable to air, only some very slight rhonchi being perceptible at the apex; the percussion-resonance was also highly exaggerated, showing the existence of an emphysematous condition of the entire lung. A consultation was now held with Dr. Jover, who suggested that there might be pneumonia of the apex, and that a pseudo-membranous plug, due to the inflammation, was obstructing the left bronchus. He proposed to order an emetic in the hope of dislodging this plug. After ipecacuanha had been given, the cough became less violent, the fever diminished, and the air entered more freely into the obstructed lung. The next morning, however, all the previous symptoms returned with as much severity as before, and this condition continued till May 24th, when the patient, during a violent fit of coughing, expectorated a hard substance, which proved to be a calculus. It measured one centimetre by seven millimetres, and was irregular, ovoid, and hollow, with a rough surface. Its weight was twenty centigrammes. On analysis it was found to be composed of carbonate and phosphate of calcium. Immediately after the expulsion of this body the air penetrated freely into every part of the left lung, the cough disappeared as if by magic, and the fever gradually diminished, till in three days' time the patient was perfectly well. The author states that this is the first case of the kind which has been reported in Cuba. Indeed, such a case as this is of extreme rarity everywhere.—*The Lancet.*

THE BOWEL LESION IN TYPHOID FEVER.—How far ought the intestinal ulceration met with in typhoid fever to be considered pathognomonic? Is the detection of ulcers in Peyer's patches, presenting none of the characters of the tuberculosis or dysentery, to be taken as proof of typhoid fever, even in the absence of well-marked clinical symptoms? Are we justified in believing in latent typhoid from post-mortem evidence alone? Such are the questions which are suggested by an interesting *brochure* recently published by Dr. Vandyke Carter, upon "A Peyerian Ulcer Lesion of the Small Intestines, apparently new" (Bombay, 1886); and the answer he would impel us to give to them would be a decided negative (*The Lancet*). The material upon which he bases his paper consists of about ten cases, in natives (in whom typhoid fever is rare) suffering from symptoms described as remittent fever, and after death, which in some cases was due to perforative peritonitis, exhibiting more or less extensive ulceration of the small intestines. Constipation rather than diarrhœa was the rule; and in not more than one case did the "fever" run the course of typhoid.

But Dr. Carter does not rely on clinical grounds to establish the non-identity between the intestinal lesion in these cases and that present in typhoid fever. He subjects the type of ulceration to a close scrutiny, and points out several prominent features of difference, the most striking being the absence in his cases of the excessive swelling and infiltration of the Peyer's patch that precede the stage of ulceration in typhoid fever. He inclines to the belief that these non-specific ulcers are produced by embolic or thrombotic plugging, and that this depends on septic conditions. That septic causes are adequate to produce intestinal lesions of this kind is not to be gainsaid; and we think that Dr. Carter has made out a case for further investigation. At the same time, with the knowledge we have of the various forms assumed by typhoid fever, or at any rate by cases classed together as typhoid, and the great variety and extent of the intestinal lesion in cases of this disease, we may hesitate at first to accept his conclusion. A less cautious observer than Dr. Vandyke Carter would doubtless have been satisfied with the detection of the numerous ulcers in the favored seats of election and the occurrence, in many cases, of perforation, to declare that the cases came under the head of typhoid fever, modified, it may be, by the conditions under which the disease occurred. Hitherto we have been led to rely upon the ulceration of the intestines as the only positive criterion of this disease; but now it will be necessary to review our position in regard to it, and it may be that we shall have to fall back upon the detection of the typhoid bacillus to determine the diagnosis.

Honors to a Medical Publisher.—King Humbert, of Italy, has recently nominated Signor Giovanni Jovene, publisher of the *Riviste Clinica e Terapeutica*, and of many medical works, to the rank of Chevalier of the Italian Crown. The title is accorded in consideration of the great impulse which Signor Jovene has given to science in Italy by the publication of so many important scientific works. We congratulate Signor Jovene, and wish him many years to enjoy the honors which he has so well deserved.

Lanoline and Cutaneous Absorption.—It is commonly stated and generally supposed that lanoline favors cutaneous absorption. But M. Aubert asserts that his experience is absolutely contradictory to this belief. So far from favoring absorption, he says, it prevents it almost wholly. In consequence of this, as lanoline does not spread over the skin, but adheres strongly to the part to which it is applied, and as it is not absorbed, he advises that it be used as a vehicle for antiseptic substances in surgical practice.

Absence of the Patella.—M. Redard reported at a meeting of the French Surgical Congress a very rare anomaly in the person of an infant who presented a congenital absence of one patella. The patella on the other side was present and normally formed.

Treatment of Catarrh of the Antrum.—M. Combe recommends trephining in the treatment of chronic catarrhal inflammation of the antrum of Highmore, and subsequent disinfection by iodol, which, on account of the absence of odor, is preferable to iodoform in such cases.

In an Article on "Indications and Contraindications for Laparotomy," Dr. J. R. Nilsen makes some very strong arguments against indiscriminate laparotomy. He gives the following sketch: "Dr. A, we will suppose, has a large hospital service; his patients come from among the poorer classes. Before entering the hospital, have they all been able to engage physicians who had it in their power to try all known modes of treatment, or several of them, or any of them? Here is Mrs. Malony, very ill, and very poor. She went to Dr. B three times, and then her means gave out. Dr. B advised her to go to a dispensary; she did (and, unfortunately for her, not to the Post-graduate). She came into the hands of Dr. C, who found a large, tender uterus, great tenderness in the parametrium on both sides, and a swelling-like something where the ovaries and tubes should lie, and so he put down in his case-book: 'Hyperplasia of the uterus; chronic oöphoritis, with disease of the Fallopian tubes;' painted a large figure with iodine upon the vaginal wall twice a week for two months, and told her to take a hot injection twice daily, without telling her how or how long to take the douche. After the two months he thought her a little better, but still she remained pretty bad. 'Would Mrs. Malony be willing to undergo an operation? Everything else had failed.' Indeed, she would. 'Anything to get well.' So she was sent to the ward of Dr. A. 'Gentlemen, I shall to-day perform laparotomy upon this patient, who was brought here last week by Dr. C for the removal of her ovaries and tubes, which are probably far advanced in disease, and give her constant intolerable suffering, even after all other means have been systematically used without the slightest effect.' So Mrs. Malony has them removed. One more successful laparotomy—done as a last resort. How much of the bulk of our statistics is made up of similar cases, and how long after their discharge as cured are the patients watched carefully?"

Medical Requirements in Virginia.—A correspondent from Washington takes exception to an item, taken from the *Virginia Medical Monthly*, appearing in a recent issue of The Medical Record, in which high praise was given to the Virginia Board of Medical Examiners. He encloses a prescription written by a practitioner in Virginia. The prescription calls for two grains of sulphate of strychnine and five drachms of citrate of iron and ammonium, and one ounce of aromatic sulphuric acid in seven ounces of water. The handwriting is not very good, and the writer betrays a lack of accurate knowledge of Latin terminations. But he is by no means peculiar in this respect, and his medical attainments may well be of such a character, despite other deficiencies, as to entitle him to receive a license from the Board.

A Large Child.—Dr. R. Cyrene McDonald, of Boston, writes that he attended a woman in her first confinement on December 2, 1886. The child, when born, was of ordinary size. On May 1st the infant was measured, with the following results: Head, 17½ inches; shoulder, 20½; waist, 18¾; upper arm, 7¾; forearm, 6; thigh, 10; leg, 7. The length of the child was twenty-six inches and its weight twenty-one pounds. Dr. McDonald reported a similar case in these columns not long ago.

A Solvent for Antifebrin.—Dr. Proegler, of Fort Wayne, Ind., writes that he has used the aromatic spirits of ammonia as a solvent for antifebrin, and has found it very good for that purpose. It was suggested to him by Mr. Louis Schmidt, a pharmacist of that city.

Almén's Test for Sugar.—In the formula given by Dr. Norderling in The Medical Record of April 23, 1887, of Almén's test for sugar, the equivalent of potassio-sodium tartrate should read Gm. iv. (℥ j.), instead of ℥ iv., as printed.

Novelists and the Medical Profession.—In that clever and interesting novel by Maxwell Gray, "The Silence of Dean Maitland," which, though bearing this year's date, has already reached a fourth edition, there is, says *The Lancet*, a graceful allusion to the medical profession, the members of which receive but scant justice from novelists in general: "The medical profession, strangely enough, has never been popular, skill in the healing art being usually attributed by the unlearned to the favor of the evil one; a clever physician is prized and feared, but rarely loved. Even among the cultured there still lingers a faint repulsion for the man who is the only welcome guest in the day of sickness and peril, and society is only just beginning to honor the cultivated intellect and recognize the social value of the doctor." The real hero, and certainly the finest character in the book,

Henry Everard, is a young surgeon, and when asking his clerical friend, Cyril Maitland, the future dean, for the reason why clergymen were more popular than doctors, received a reply in which the truth is somewhat satirically given: "Clergymen are of no use save at two or three august moments of life—when a man dies, gets married, or is born; therefore they inspire popular reverence as belonging to the ornamental and superfluous portion of existence, its fringes, so to speak. Doctors, on the contrary, cannot be dispensed with; their services are needed and obtained on the most homely occasions, and men never reverence the indispensable. Bread and cheese are taken as a matter of course, but the champagne of festivals is thought much of."

The Sixth International Congress for Hygiene and Demography.—The Congress will be held this year in Vienna, commencing on September 26th and closing on October 2d. During the continuance of the Congress there will be an Exposition of all publications, photographs, maps, models, apparatus, etc., relating to hygiene. Among those who are announced to read papers or to take part in the discussions are MM. Brouardel, Paris; v. Pettenkofer, Munich; Corradi, Pavia; Humphreys, Memphis; Inama-Sternegg, Vienna; Hueppe, Wiesbaden; Marchiafava, Rome; Beaujon, Amsterdam; Körösi, Budapest; Semmola, Naples; Proust, Paris; Bohm, Vienna; and many others. The address of the Committee of Organization of the Congress is I., Renngasse, 20, Vienna. On the programme of social events are excursions to the "Höllenthal," to Kahlenberg and to Budapest.

Almén's Test for Sugar.—Of all tests for sugar in urine, Fehling's is undoubtedly the most satisfactory. The only objection that can be urged against it is the difficulty of preserving it a sufficient length of time, so that unless recently prepared it may lead to fallacious results, owing to stale solutions having a tendency to throw down the suboxide of copper spontaneously when heated. This, of course, is a great disadvantage to practitioners, who may be seldom called upon to use the test, and are at a distance from manufacturing chemists from whom they may procure a fresh supply. To remedy this Professor Almén, of Upsala, has improved the old bismuth test for sugar, and has prepared a solution which has the advantage of keeping unchanged for years and being at the same time an extremely delicate test for sugar in urine (*The Lancet*). It consists of a solution of bismuth subnitrate, with caustic soda and potassio-sodium tartrate. In testing for sugar, the albumen, if present, must be first removed by precipitation by heat and acid, and one part of the solution treated with ten of the urine, when, if sugar be present, the bismuth will be deposited in a metallic state. The test is sufficiently delicate to detect sugar in the proportion of only .05 per cent. This test, as we have already said, is chiefly valuable on account of its preservative qualities, keeping well on board ship and in hot climates, though we doubt if it will supersede the use of Fehling's solution, especially as the latter is now supplied in hermetically sealed capsules which preserve the test for a considerable time.

Dental Disease in Savages.—Dr. Whitney, writing from Honolulu, describes, in the *British Journal of Dental Science*, the bleached skeletons of Kauai, and points out that it is a great mistake to believe the "noble savage" enjoys an immunity from suffering due to disease affecting his teeth; in spite of the simple nature of his food and his out-door life, he still has toothache. Dr. Whitney found both superior and interior maxillaries, but none had complete dentures. This does not take into account the loss of the anterior lower, and, less frequently, upper teeth, which were knocked out to express their grief at the death of a favorite chief, as was their universal custom in those times. Some had lost but one or two teeth, others the greater portion of the molars; while not infrequently the anteriors showed decay upon their surfaces, or had left the traces of alveolar abscess. In several cases traces existed of much suffering, caused by the eruption of the inferior third molars, and in several by the superior. One specimen showed the ravages of salivary calculi, but, as a general rule, there was but little tartar upon the teeth. No instances of erosion were met with, but many of the teeth were much worn by use. There was one case of anchylosis of the jaw. Several had oxostosis. The effects of alveolar abscess were very frequently seen, sometimes leaving but a small opening through the outer plate of the jaw, in others the whole outer plate being gone. Dr. Whitney found the antrum to vary greatly in size. On the whole, the teeth were set in a regular arch, but there were a few instances of irregularity. In uncovering two skeletens lying side by side, it was seen that both were females, one much older than the other, and in them the peculiar dental irregularity of the one was exactly repeated in the other.—*The Lancet.*

A New Instrument for the Relief of Deafness.—An interesting demonstration of certain new instruments for the improvement of the hearing of the partially deaf was made before the last meeting of the College of Physicians, and repeated at a recent meeting of the County Medical Society. The instruments were those devised by Mr. Maloney, Washington, D. C. In these instruments there is no tube to enter the meatus and thus obstruct the entrance of the sound-waves. A tightly stretched rubber membrane, about two inches in diameter, is secured between two rings and enclosed in a hard rubber box, which is applied against the external ear. To the outer portion is attached a cone-shaped tube for collecting the sound-waves. The vibration of the rubber membrane sets in vibration the air contained in the external auditory canal. One form of the apparatus consists of the ear-piece just described, to which is attached a flexible rubber tube, terminating in a mouth-piece. This modification is intended to be used in the training of the partially deaf, the speaker applying his mouth to the mouth-piece and speaking in the tube while the listener applies the other extremity to his ear. The impact of the air upon the membrana tympani is prevented by the presence of the rubber membrane. In several tests made before the societies it was found that a person so deaf as to be unable to hear a loud voice was able to hear through this tube a whisper, while a person standing near the speaker and trying to catch what was said heard nothing.—*Progress.*

A Thermometer for taking Mouth Temperatures.—A new form of clinical thermometer has been devised by Mr. John Barry for taking the sublingual temperature. The modification is in the bulb, which, instead of being joined to the stem of the instrument in the same axis, is at right angles to it, and is slightly curved on itself. By this means the thermometer lies more securely and conveniently under the tongue, and a greater surface of the bulb is in contact with the mucous membrane.

Treatment of Laryngeal Phthisis.—At a recent meeting of the Société Médicale des Hôpitaux, M. Gouguenheim described the results obtained by M. Ehring by his surgical treatment of tubercular laryngitis. This consists in scraping and cleaning the ulcerations, or, when this is impracticable, in making lactic acid or iodoform injections under the laryngeal mucous membrane after the application of cocaine. Of two hundred patients thus treated last year, twenty-eight were cured. M. Gouguenheim showed specimens which proved that tubercular ulcers had been cured. The nature of the disease was established by the presence of the characteristic bacillus in the microscopic preparation which had been examined by Professor Virchow. M. Labbé said these statements embodied facts of an extraordinary nature, which could not be accepted without reserve.

NEW METHODS OF APPLYING THE PLASTER-OF-PARIS JACKET TO OBTAIN EXTENSION, WITH ILLUSTRATIVE CASES.

By W. R. WHITEHEAD., M.D.,

DENVER, COL.

THE infrequency and grave character of the two cases which I propose briefly to report, and the extremely different indications which called for the use of the plaster-of-Paris jacket in each case, together with the excellent results obtained, will, I believe, make the few remarks which I desire to offer of sufficient interest to elicit the attentive consideration of the readers of THE MEDICAL RECORD.

Case of pseudo-hypertrophic muscular paralysis, with exaggerated lordosis, corrected by extension with adhesive plaster, aided by a new and peculiar application of the plaster-of-Paris jacket.—Emma D——, aged three and a half years, about two years ago was noticed by her attending physician to have a commencing deformity of the spine, and he applied a brace to correct this deformity; this brace caused distress and uneasiness, and it was soon thrown aside. She was under the care of a number of physicians, and finally, about three months ago, her parents came with her to consult me. It had been alleged that she had hip-joint disease. On being undressed she presented the appearance shown as exhibited by the wood-cut Fig. 1, copied from a photograph by Rinehart, of Denver. It was soon perceived that there was perfect freedom of motion at both hip-joints, and that there was not the slightest pain on moving either thigh in any direction. The little girl, when she walked, had a waddling gait, like a duck, swaying from side to side. She experienced no pain in walking, only a weakness in her back and in her legs, and soon became tired. There was no pain along the spine; neither did jarring motions cause any pain in this part. Along the course of the erector spinæ muscles on the right side, and in the lower dorsal region, there was a manifest tenderness when these muscles were pressed—they contracted spasmodically. The gluteal muscles are apparently unusually developed, as also are the muscles of the thigh and leg, especially are the calves of the legs of unusual size. This considerable development of the gluteal region, and of the lower limbs, has excited the attention of the parents and of their friends. She stands and walks with the legs rather widely apart, and there is seemingly less power in the extensor muscles of the legs than in the flexors.

FIG. 1.

Having suspended her by the arms the deformity disappeared, as shown at Fig. 2, copied from a photograph.

The spine being free from disease, and there being no disease of either hip-joint, it of course follows that the lordosis is due to paralysis or diminished power of the erector spinæ muscles. The psoas and iliacus muscles acting from below, while the little girl is standing, draw the lumbar portion of the spine and pelvis forward, and produce the deformity observed at Fig. 1. Two indications of treatment at once suggested themselves to me; the first was to support the spine, and the second was to arrest the paralysis of the spinal muscles and invigorate those of the limbs, and for this purpose the suitable application of galvanism to improve the nutrition and to arrest fatty degeneration of the muscles I regard of equal importance with the mechanical support which I have already supplied. This electrical part of the treatment I shall apply so soon as an improved fifty-cell permanent gravity battery, which is making for me to be placed in my office, is completed, and which I much need for the treatment of paralysis attending other deformities under my care. However, the main object of this communication is to show this mechanical device for the support of the spine in this case, and which device is equally applicable to other diseases affecting the spine. Indeed, I did not at first succeed in obtaining so simple and effective an arrangement of the plaster-of-Paris jacket until after two or three trials.

FIG. 2.

My first application of this apparatus in its present form was on a patient, a consumptive, with vertebral caries, and an external opening which discharged at least half a pint of pus daily. Dr. Wm. M. Fay, of Denver, requested me to see this patient, a young man of about twenty-five years of age from New York State, in an almost exhausted condition, but having a fairly good appetite and craving to get out of doors, so as to breathe the fresh air. I was struck with the comparative ease and comfort with which he could walk, if supported under the shoulders by his wife, a strong, well-developed young lady, who was accustomed to assist him about his apartment in this manner. I suggested the use of the plaster-of-Paris jacket apparatus, and applied it; the relief was considerable, especially while standing. A hole having been made, and properly protected with oil-silk and rubber cloth during the application of the jacket, the wound was washed out each day by Dr. Fay. But the patient was in a very feeble condition, and his general health failed so rapidly that I was called to see him, and removed the jacket, or rather I cut it in front; he objected to its removal entirely, as he had experienced such relief from its use. However, a few days afterward he died.

In applying this apparatus to the little girl, the following is a brief description of its mode of application: I cut two pieces of Mead's adhesive plaster, prepared by Seabury & Johnson, each one large enough to nearly half encircle the body, and of the shape shown at Fig. 3. To the upper ends of each piece of adhesive plaster were pieces of gaiter-webbing, strongly sewed, and application loosely tied over the shoulder. Vigilant care was taken to prevent any creases or wrinkling of the plaster; and a close-fitting undershirt was then put on, and drawn smoothly over the adhesive plaster. The child having

been properly suspended, and a sufficient number of turns of wet plaster-of-Paris roller bandages applied from the armpits to the hips, over the close-fitting undershirt, then two pieces of curved steel, as shown at Fig. 4, were applied to the back, one on each side of the spine, and

Fig. 3.

Fig. 4.

fastened in place, one after the other, with additional turns of wet plaster-of-Paris bandages. Each one of these pieces of steel had been made to fit the back of the patient, and was supplied above with a roller and buckle; and below, to each piece separately, was riveted a piece of tin, like the tin of a nutmeg-grater, but rough on both sides, as in the Sayre jury-mast, except that the upright pieces of steel were not connected, and which permitted of their ready and handy application. After the removal of the pads placed over the stomach and bladder, and after the plaster jacket was dry, the two pieces of webbing on each side were drawn over the rollers of the upright pieces of *steel, and each piece of webbing separately drawn tight*, and then both buckled. This had the effect to draw the chest and shoulders upward, and by means of the upright pieces of steel, which were thoroughly incorporated with the plaster-of-Paris jacket, the jacket was pushed down on the hips, thus producing extension and counter-extension in the manner shown at Fig. 5, which is copied from a photograph, and shows the little girl standing in a perfectly erect posture, and in marked contrast to her condition as exhibited at Fig. 1. She continues to wear the apparatus with comfort and advantage, especially in walking.

Fig. 5.

On the 24th of last March a gentleman residing at Cheyenne, Wyo., who had recently seen Dr. Lewis A. Sayre, of New York City, by his advice consulted me concerning his little son, aged about four years. Dr. Sayre had not seen the child, and knew of his condition only from the father's relation of the case to him. The father, Mr. M——, with the child and his mother, came to my office, but not until after having, at the earnest solicitation of a friend, previously seen a certain prominent physician, who, on seeing the little patient, declared that he had hip-joint disease, and at once, as the father states, proposed a hip-joint splint for his child. By a careful examination it was made quite evident that there was not the slightest sign of any disease about either of the hip-joints, and the forcible and rapid manner in which I moved the femurs in their sockets, without any pain whatever, fully satisfied the parents also. Neither was there any evidence of disease of the bones of the spine, as no jarring motions, on other tests that I subjected him to, affected him in the least. The boy was apparently in excellent health and seemingly well developed, except that there was an unusual muscular development, for a child, about the lower limbs, and a slight lordosis. It was probably this curvature of the lower part of the back that misled the prominent doctor referred to, inducing him hastily to believe, without examining into the motion at the hips, the case to be one of hip-joint disease. This boy had a waddling motion in walking; he stood with his legs widely apart, and was weak in his lower limbs. On suspending him by the arms the lordosis disappeared. The feet were disposed to turn in slightly, and the peroneus longus and brevis muscles responded somewhat feebly to the faradic current. I thought the case one of pseudo-hypertrophic muscular paralysis, and similar to the one just described, but in a less advanced stage. At this time, however, I had not yet fully decided upon the merits of my plaster-of-Paris jacket extension apparatus. I recommended massage, and the future careful and intelligent use of galvanism, and requested the father to see me again, with his child, in about a month or six weeks.

Case of fracture of the pelvis, and upward dislocation of the iliac bone at the sacro iliac articulation; two inches of shortening of the left leg; treated successfully without shortening, by downward extension from the hips, with weights and pulleys attached to a plaster-of-Paris jacket. —Mr. F—— some weeks ago accidentally fell from the railing on the top floor of one of our public buildings—the Chamber of Commerce—fracturing the pelvis, the right ulna, and sustaining a number of other serious injuries. He was conveyed to the Arapahoe County Hospital, at Denver, and about ten days or two weeks after receiving these injuries I was requested by Dr. H. W. McLauthlin, the attending physician of the hospital, to see him. There was a shortening of the left leg of two inches. Every movement of the pelvis was extremely painful; there was extensive ecchymosis about the perineum, and of the upper part of the left thigh, both in front and behind. The horizontal ramus of the pubes on the left side was distinctly felt to be fractured and displaced, and probably the ascending ramus was also fractured. In the region of the sacro-iliac symphysis there was a considerable prominence, forming a somewhat flattened lump of the thickness of a man's wrist. Mr. F—— is a stout, heavy man, about five feet eight inches in height, and about one hundred and sixty pounds in weight. There was present a nurse, a German, of herculean strength and proportions, and who, at my request, suspended Mr. F—— under the arms, as I suspended the little girl, as shown at Fig. 2; immediately the lump at the sacro-iliac articulation and the shortening of the leg disappeared. A day or two afterward I had Mr. F—— properly suspended, with his toes slightly touching the floor, and applied a plaster-of-Paris vestment, or jacket, investing the hips from the waist downward. While so doing I passed around the body, above the hips, on each side and separately, two turns of a double roller bandage; I tied each one on the side and flattened the knots, leaving the ends of each double roller bandage hanging on the outside of each thigh, like the ends of a sword-sash, to which I subsequently tied cords for extension weights. Finally, with additional turns of wet plaster-of-Paris bandages, I completed the plaster-of-Paris vestment of the hips. The patient was gently lowered, and placed on a hard mattress, the pads over the bladder and stomach were removed, and he was put to bed, with the foot of the bed raised, and a twelve-pound weight on each side, attached to the plaster-of-Paris jacket. A day or two afterward he was removed

to his home, where I attended him, increasing the extension weight a few pounds. Yesterday, after five weeks of confinement in the plaster jacket, I removed it—the deformity no longer exists; neither is there any shortening of the leg. He turns with great freedom and ease in bed, and after recovering from a slight attack of dizziness on attempting to get up, he stood on his feet erect, and was able to make a few steps. He is quite stiff about the back and hips, but he will, I believe, be able in a week or ten days to walk quite as well as before the fracture and dislocation.

PASSIVE MOTION IN THE TREATMENT OF PARALYSIS OF THE OCULAR MUSCLES.[1]

By CHARLES STEDMAN BULL, M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO THE NURSERY AND CHILD'S HOSPITAL, AND TO ST. MARY'S FREE HOSPITAL FOR CHILDREN.

The treatment of paralysis of the ocular muscles is, even under the most favorable circumstances, unsatisfactory, and the longer the muscles have been paralyzed the more unsatisfactory are the results of treatment, whether by internal medication or external applications or galvanism. Many cases of syphilitic paralysis improve up to a certain point and then the improvement stops, and though the paralyzed muscle or muscles may have regained some of their motility, the annoying diplopia still remains. Other cases are not improved at all, in spite of all the methods of treatment at our disposal. Cases of rheumatic paralysis are even more obstinate in resisting treatment, and it is in this class of cases, more than in any other, that the method of treatment first suggested by Michel in 1877 has proved, in the writer's experience, most useful. The influence of the galvanic current is most uncertain in producing the desired effects, mainly because it is, in the nature of things, almost impossible to localize or concentrate its action upon the paralyzed muscle, owing to a diffusion of a large part of the strength of the current through the overlying and surrounding tissues. By the ordinary method of application one pole, usually a moist sponge, is placed over the closed lids, and the other pole is placed at the nape of the neck. Here a portion of the strength of the current does undoubtedly pass through the paralyzed muscle, but the greater part is diffused through the tissues of the lids and conjunctiva, and does not pass through the affected muscle. The same disadvantage attaches to the method advocated by De Wecker, in which the positive pole is placed over the supra-orbital or infra-orbital foramen, according to the position of the muscle involved, while the negative pole, an olive-shaped electrode, is passed over the eye, the lids being closed, in the direction of the paralyzed muscle. Direct stimulation of the muscular fibres by means of a small electrode passed through an opening made in the conjunctiva, and brought directly in contact with the muscle in its sheath, produces perhaps more contractility in the muscular fibres, but always causes considerable pain, and sometimes great irritation and congestion at the point of contact. Hence this method of direct stimulation of the paralyzed muscle has been given up in favor of the indirect or reflex method.

In the *Klinische Monatsblätter für Augenheilkunde* for November, 1877, Professor Michel proposed an orthopedic method of treatment of the paralyses of the ocular muscles, which was novel in conception and offered theoretically certain advantages. It was based on the principle of passive motion, and was very simple in execution. The paralyzed muscle is to be seized at its line of sclerotic implantation with a pair of ordinary fixation-forceps, and the eyeball is then to be pulled backward and forward in the direction of the line of contraction of the affected muscle, as far as possible toward or even beyond the limit of contraction, and then back in the reverse direction as far as the limit of extreme relaxation, and these to-and-fro movements are to be continued for about two minutes. According to Michel the effect produced is greatest immediately after these manipulations, and sometimes the increase in contractility amounts to a millimetre and a half. The effect gradually diminishes until in about an hour it corresponds to a prism of twelve to sixteen degrees in strength. Michel states that the pain produced was trifling, and that the induced conjunctival irritation soon subsided under cold applications. He recommended a daily performance of the manœuvre, and called attention to the considerable resistance at first offered to the manœuvre by the antagonistic muscle. The advantages claimed by Michel for this method were: 1, Elimination of the action of the antagonistic muscle; 2, the brief duration of the treatment. Since the appearance of Michel's article the writer has tried this method of passive motion in a number of cases, and now gives the result of his experience in twenty-one cases, as follows:

I. *Paralysis of external rectus; secondary convergent squint.*—Mr. M. F——, aged thirty-five; December 17, 1877. Has had homonymous diplopia for several weeks, and an examination showed paralysis of right external rectus and a slight tendency to convergent squint; also a rather marked weakness in action of the internal recti muscles. Vision normal, fundus healthy. No history of either syphilitic infection or rheumatic tendency. Attributes the muscular paralysis to a severe cold. Internal administration of potassium iodide and application of the galvanic current three times a week, though persisted in, gave no result. Passive motion of the right externus daily, for a minute and a half to two minutes, caused in nine days a complete recovery. The pain caused was very severe, and the conjunctival irritation remained for several weeks after the last application.

II. *Paralysis of internal rectus.*—Mrs. B——, aged thirty-one; June 25, 1878. Crossed diplopia for some months. Paralysis of right internal rectus almost total. Patient is remarkably rheumatic. V. = $\frac{20}{30}$ +, unimproved. No trouble with eyes until the diplopia appeared. No history of syphilis. At first a mixture of potassium iodide and sodium salicylate, combined with the galvanic current, seemed to bring about a certain improvement, but after a few weeks this ceased, and the case remained at a standstill. Passive motion daily for a period of two minutes was then instituted, and an improvement began almost immediately. At the end of the twelfth session the diplopia had entirely disappeared, and the motility was apparently restored. This patient also complained greatly of the pain, and after several of the visits there was a distinct subconjunctival extravasation of blood.

III. *Paresis of superior rectus and external rectus.*—Miss H. S——, aged seventeen; November 29, 1878. Two weeks ago was attacked with severe pain in right eye and orbit, and right side of head, and after some hours diplopia appeared, and still exists. Pain at irregular intervals. Is a tall, pale, anæmic girl, subject to rheumatism. Diplopia is homonymous, and one image stands higher than the other. V. and fundus normal. Examination showed a paresis of the right superior rectus and external rectus. The internal administration of iron and bark, and the daily application of the galvanic current, soon brought about a cure of the paresis in the superior rectus, but the external rectus remained paralyzed in spite of everything that was done. It was then decided to try passive motion, and the external rectus was pulled backward and forward daily for a period of one minute, causing the patient very severe pain, so that, after the fifth session, it was deemed advisable to use the passive motion not oftener than every second day. This was kept up, but at

[1] Read before the American Ophthalmological Society, New London, July 20, 1887.

the end of the second week it became necessary to stop it altogether, on account of the irritation and pain which it occasioned. Considerable motion, however, had been regained in the paralyzed muscle.

IV. *Paresis of inferior rectus.*—Mr. A. W. T——, aged forty; October 7, 1880. Chancre fourteen months ago, followed by cutaneous and glandular lesions. Mucous patches on tongue and in mouth and nose. Five weeks ago diplopia appeared. Examination showed paralysis of right inferior rectus muscle. V. and fundus normal. Prolonged administration of mercury and potassium iodide, together with the application of the galvanic current, failed to produce the slightest effect upon the paralyzed muscle. Passive motion was then instituted, with daily sessions of two minutes, which proved very painful, but also almost at once brought about an improvement in the paralyzed muscle, and at the end of the tenth session the paralysis had disappeared.

V. *Paresis of external rectus.*—Mr. F. D. S——, aged thirty-two; December 3, 1880. Is rheumatic to a marked degree. Four months ago, while travelling in the West, he was caught in a storm and laid up with an attack of rheumatism, and during the attack the diplopia suddenly appeared. Examination showed paresis of right external rectus. V. and fundus normal. Potassium iodide and sodium salicylate, with the galvanic current every second day, produced considerable amelioration in the paralysis, but after the first two weeks there was no further improvement, though the treatment was persisted in for a month. Passive motion was then instituted daily, and a further improvement began at once. After a month's treatment the motility of the eye seemed restored, though diplopia exists at the extreme right of the field.

VI. *Paralysis of internal and external recti.*—Mr. J. P. W——, aged twenty-one; March 28, 1880. Has had for three years complete paralysis of left internal rectus, and partial paralysis in left external rectus, origin unknown. Present condition about what it was when the trouble began. Refraction hypermetropic. V. and fundus normal. Slight divergence of right eye. This patient had a long and faithful trial with the galvanic current and potassium iodide, and some improvement was produced in the paresis of the external rectus, but the paralysis of the internal rectus remained complete. Passive motion of the latter muscle was then begun, and carried out daily for nearly a month, but no improvement followed. This patient bore the manipulation extremely well.

VII. *Paresis of external rectus.*—Mr. G. B. B——, aged thirty-seven; April 23, 1881. Homonymous diplopia when looking to right of median line, for several weeks. Partial paralysis of right external rectus. Subject to muscular rheumatism. V. and fundus normal. No history of syphilis. Galvanism in this case proved absolutely useless, and there was no perceptible improvement from the administration of soda or potash. But three applications of passive motion on succeeding days produced a complete cure of the paresis and the disappearance of the diplopia. This patient complained greatly of the pain, and the conjunctiva remained congested for several weeks after the treatment ceased.

VIII. *Paresis of inferior rectus.*—Mr. J. R——, aged forty-one; June 6, 1881. Chancre seven years ago; numerous constitutional symptoms since. Has had two attacks of diplopia before this one, from both of which he entirely recovered, except that there still remains partial ptosis of right eye. Present attack of diplopia began a month ago, and examination shows paresis of right inferior rectus. V. and fundus normal. The persistent administration of potassium iodide in rapidly increasing doses and the daily application of the galvanic current proved of no avail, and the same result followed the employment of passive motion carried on daily for a month.

IX. *Paresis of internal rectus.*—Mr. R. H. F——, aged seventeen; February 20, 1883. Crossed diplopia for three months. Paresis of right internal rectus, traced directly to exposure for hours to severe cold. V. = $\frac{20}{20}$, fundus normal. Has had some pain, not very severe, in right eye and orbit. Galvanism and hot water caused a temporary improvement, but on the tenth day the condition was as bad as when the patient was first seen. Passive motion, however, acted extremely well in this case, and at the end of the seventh application the diplopia had entirely disappeared and the patient was discharged. This patient did not complain much of pain.

X. *Paresis of external rectus.*—Miss C. M. C——, aged eighteen; October 23, 1883. Has convergent squint in left eye, due to paralysis of external rectus of same eye, of nearly two years' duration, which has remained unchanged in spite of continuous internal medication and galvanism. V. = $\frac{20}{30}$, media clear, and fundus healthy. This case was deemed a very unfavorable one from the beginning, owing to the length of time the paralysis had existed. There was a slight improvement in muscular power of the external rectus during the first few sessions of the passive-motion method, but no subsequent improvement whatever, and after two weeks the treatment was discontinued.

XI. *Paresis of external rectus.*—Mrs. J. T——, aged forty-three; November 30, 1883. Long subject to rheumatism. Two years ago had an alveolar abscess in upper jaw on right side, which opened inward and outward through cheek. One month ago had diplopia, which examination shows is due to paresis of left external rectus, with secondary contraction of internal rectus. V. = $\frac{20}{20}$, media clear, fundus normal. This patient had gone through a long course of anti-rheumatic treatment, including sulphur and other medicated baths, without any effect being produced upon the paralyzed muscle. Eleven daily sessions of passive motion produced considerable improvement in the action of the external rectus, but the diplopia persisted even after division of the internal rectus.

XII. *Paralysis of external rectus.*—Miss M. K. J——, aged thirty; February 21, 1884. Diplopia and convergent squint in right eye, following paralysis of external rectus. V. = $\frac{20}{20}$, media clear, and fundus normal. No history of either rheumatism or syphilis. Galvanism proved of no avail, though employed for six weeks. The internal rectus muscle was then divided, and at the end of a week passive motion was begun, daily sessions of two minutes each being held. Improvement began at once, and after six applications the diplopia disappeared and did not return. There was a slight apparent divergence of the axis resulting, but no diplopia, and the internal rectus acted well.

XIII. *Paresis of internal rectus.*—Mr. E. J. B——, aged twenty-four; October 29, 1884. Had paralysis of right internal rectus nearly two years ago, with diplopia and secondary contraction of external rectus, from which he has partially recovered, but diplopia is still annoying. V. normal, fundus healthy, optic axis still divergent, but the right can be turned somewhat to the left of the median line. Daily applications of passive motion for two minutes during two weeks produced a decided improvement in the power of the internal rectus, so that double images appeared only on the extreme left. No further improvement, however, was perceptible after the end of the second week, and the treatment was stopped.

XIV. *Paresis of external recti muscles.*—Mr. L. O——, aged sixteen; March 7, 1885. Convergent squint appeared in both eyes some months ago, with annoying diplopia. Both external recti muscles are affected, but not entirely paralyzed. Attack preceded by pain in the eyes and orbits. V. = $\frac{20}{20}$, media clear, but fundus of both eyes seem abnormally injected. This was the first case in which cocaine was employed, and the relief from pain was a very great advantage. Daily employment of passive motion was continued for three

weeks, and produced marked improvement in the motility outward of left eye, and to a less degree in the right eye. But the diplopia still continued, though to a much less annoying degree. There still remained a slight convergence in the right eye, but no further improvement was gained and the treatment was given up. The galvanic current was subsequently employed every second day, and under its influence the right external rectus continued to improve in motility, but after three months slight diplopia still continued and all treatment was stopped.

XV. *Paralysis of external rectus.*—Mr. G. W. W——, aged thirty; December 27, 1885. Chancre four years ago. Constitutional symptoms, one attack of iritis in right eye. Three months ago diplopia made its appearance and remains. Has complete paralysis of right external rectus. V., media, and fundus normal. Slight convergence of the right eye. Potassium iodide and mercury had been previously tried, but produced only slight temporary benefit. The potash was again essayed in large doses and pushed to toleration, but caused no appreciable improvement in the external rectus. Very decided improvement, however, followed the daily employment of passive motion for from two to three minutes, and continued for sixteen days. Here all improvement stopped, leaving still a loss of power in the externus of about twenty degrees, and of course a corresponding diplopia. Galvanism in this case proved useless. Cocaine did not entirely relieve the pain in this case.

XVI. *Paresis of inferior rectus.*—Mr. H——, aged forty-nine; March 17, 1886. Is rheumatic, but denies syphilis. Eight years ago had an attack of diplopia which lasted several months. Three years ago had paralysis of the left arm, from which he entirely recovered. Three months ago had a second attack of diplopia, which still exists. Vision, media, and fundus normal. Examination shows a paresis of the right inferior rectus. Galvanism and sodium salicylate in large doses produced some slight improvement. Passive motion under cocaine produced absolutely no effect whatever in increasing the power of the muscle or in diminishing the annoying diplopia.

XVII. *Paresis of external rectus.*—Mr. F. A. W——, aged thirty-five; April 11, 1886. Diplopia originally came three years ago, from paralysis of external rectus muscle of right eye, and secondary convergent squint. The paresis is still present, though there has been considerable improvement. Media clear; R. E., $\frac{20}{70}+$; L. E., $\frac{20}{20}$. Refraction hypermetropic. Galvanism proved useless in this case, though faithfully persisted in for about six weeks. Passive motion under cocaine, employed daily, produced considerable improvement in the movements of the external rectus during the first six sessions, but after this proved valueless, the diplopia remaining.

XVIII. *Paralysis of external rectus.*—Mrs. C. W. I——, aged forty-eight; November 2, 1886. Long subject to rheumatism. Nine years ago, after a very severe attack of pain in right eye and orbit, diplopia came on and persisted ever since. Examination showed complete paralysis of the right external rectus and secondary contraction of internal rectus. Refraction hypermetropic. V. normal, media and fundus healthy. Galvanism was faithfully tried, but failed to produce any effect. Passive motion daily, under cocaine, proved equally valueless, and after twelve applications was given up.

XIX. *Paresis of external rectus.*—Mrs. T. P. K——, aged thirty-five; December 7, 1886. For many years she has not been able to turn her eyes to the right side without seeing double, and she habitually carries her head to the right side. Examination shows paresis of right external rectus. Refraction hypermetropic and astigmatic. Media and fundus normal. V. normal when the refractive error was corrected. Tenotomy of the right internus and daily employment of passive motion under cocaine produced no effect whatever in improving the power of the external rectus, and after sixteen daily applications all treatment was discontinued.

XX. *Paralysis of external rectus; secondary convergent squint.*—Miss S. T.——, aged nineteen; February 2, 1887. Homonymous diplopia, but ill-defined for two months. Examination shows complete paralysis of the right external rectus, probably as a result of exposure to cold. Both corneæ cloudy from old ulcerations in childhood. R. E., $\frac{20}{50}$; L. E., $\frac{20}{100}$. This patient had been treated continuously by potassium iodide and the galvanic current since the appearance of the diplopia, but without any result. Daily passive motion for two minutes under cocaine produced a complete cure in nine days.

XXI. *Paralysis of internal rectus.*—E. R——, aged twenty-seven; March 18, 1887. Diplopia and divergent squint in right eye for more than a year. Examination shows paralysis of right internal rectus. R. E., V. $\frac{20}{100}+$; L. E., $\frac{20}{20}$. Media clear, fundus healthy. Refraction slightly myopic, which corrected in right eye gave normal vision. Seven daily applications of passive motion for two minutes each day caused a disappearance of the diplopia and return of motility in the paralyzed internal rectus.

In considering the results of treatment by passive motion in these twenty-one cases, it will be seen that the paralysis was entirely cured in eight cases, partially relieved in six cases, while in seven cases the treatment proved valueless. This is certainly no very brilliant showing, and yet the results are sufficiently favorable to make it advisable to continue our efforts in this direction. A more extended experience may perhaps teach us that passive motion in connection with the careful application of the galvanic current may give us better results than heretofore in the treatment of paralysis of the ocular muscles of long standing.

Michel reports in detail one case in which a recovery took place in five weeks. Spalding (*Arch. of Ophthal.*, xv., 4) reports four cases, of which two recovered within three weeks and two were failures. Alt (*Amer. Jour. of Ophth.*, April, 1887) reports five cases, of which three recovered and two were failures.

The pain caused by the manipulation when no anæsthetic is used is in most cases severe, and is by no means entirely relieved by cocaine. The conjunctival irritation caused by the treatment is considerable, but usually transient. In several cases more or less extensive extravasation of blood took place beneath the conjunctiva, which, however, was readily absorbed. In three cases a rather pronounced œdema or chemosis of the conjunctiva followed the manipulation; but all these symptoms were transient in duration and limited to the region involved in the manœuvre. An attempt was made to substitute a pair of smooth-pronged forceps, something like the ordinary epilation-forceps, for the toothed fixation-forceps, in order to diminish the pain and cause less laceration of the conjunctiva, but such forceps proved useless, as they failed to take hold of the muscle and constantly slipped when traction was made.

Cocaine in Inflamed Tissues.—Dr. J. R. Campbell, of Newton, N. C., says that a writer in a recent issue of The Medical Record was incorrect in his statement that cocaine is useless when injected into inflamed tissues. He writes that he recently had occasion to incise a thumb for a neglected case of whitlow. Five minims of a ten per cent. solution of cocaine were injected into the ball of the thumb, and a like quantity just in advance of the second joint in the line of proposed incision. A bistoury was passed slowly and carefully down to the bone, and although the patient was a very nervous young lady, she felt no pain, and thought, until she looked at the thumb, that the operator had been merely paring the nail.

THE ABORTIVE TREATMENT OF FURUNCLES.

By LOUIS HEITZMANN, M.D.,

NEW YORK.

Although the treatment of furuncles has received a great amount of attention, we must admit that it has so far been rather unsatisfactory. We have not been able to relieve the enormous painfulness at the commencement of the affection very quickly, nor has it been possible to materially shorten the course of the disease. A great many different remedies have been tried, but with no very encouraging results.

The causes of furuncles are, as is generally supposed, various, and it has been customary to divide them into idiopathic and symptomatic. The idiopathic furuncles are the results of different irritations to the skin; the symptomatic occur either in the course of general systemic derangements, or are the results of them. I believe it would be much better if we were to divide the causes into direct and indirect. The direct cause is the Staphylococcus pyogenes aureus, which was first described as being present in furuncles by Garré, about two years ago; the indirect ones are those mentioned above. Recent and most careful researches of several bacteriologists, especially of Rosenbach and Passet, have shown that, with the exception of only a very few substances, such as turpentine and mercury, neither mechanical nor chemical irritants will produce suppuration without the presence, at the same time, of micro-organisms. Some authors deny even these exceptional cases, and say, "No suppuration without micro-organisms." Whether this axiom is correct or not we will not investigate here, but that the Staphylococcus pyogenes aureus is the real cause of the furunculous inflammation has again recently been proven by an experiment of Garré upon himself, in which he rubbed into the perfectly healthy skin of his arm several staphylococcus colonies taken from osteo-myelitic pus, and these, penetrating the excretory ducts of the cutaneous glands, produced furuncles in large number.[1]

Before I discuss the treatment of boils, I would like to mention the so-called predisposition to furunculosis. It is taught in many, especially in American text-books, that a disposition to the formation of furuncles is more or less necessary. This view fortunately loses more and more adherents, and to-day there are probably few physicians who will doubt that furuncles can be formed without predisposition, even in the healthiest person. According to what was said above, it is sufficiently clear how boils originate, and why they are so often present in the course of itching or pustular skin-diseases, such as eczema, scabies, phthiriasis corporis, prurigo, or acne. The disposition, in connection with internal derangements, such as diabetes, tuberculosis, uræmia, etc., can also easily be explained, if we remember how easily vulnerable the skin is in such affections.

Taking into consideration such extremely different views in regard to the etiology of furuncles, we cannot be surprised that the internal treatment has been so various. It would lead too far were I to attempt to enumerate all the modes of treatment and medicines that have been used; and still, in spite of the great number, we cannot deny that we have so far not been able to prevent the formation of furuncles nor to abort them. The simplest treatment at the commencement of the affection was the application of cold or moist heat, according to the effect in each individual case or the sensation of the patient, for the course can be shortened neither by the one nor by the other. Another, but certainly not very agreeable method, was the application of caustics, of which quite a number have been recommended, but more especially caustic potash and solid nitrate of silver. Paintings with tincture of iodine, sesquichlorate of iron, carbolic acid, the use of mercurial ointments, and a good many others were tried, but without the desired effect. Lassar recommends scooping out at the very commencement of the disease; he uses small spoons, with which he opens and scoops out circumscribed suppurating cavities, especially furuncles. In 1873 Hueter recommended parenchymatous injection and infusion of carbolic-acid into inflamed tissues, but since this method was not specially recommended for furuncles, it was very soon forgotten till it was more recently again taken up by Bidder.[1] Bidder uses injections of a two per cent. carbolic acid solution, and has successfully treated 100 cases. He makes several punctures according to the size of the furuncle, and says that the feelings of pain when the injections are made are, in most cases, only slight; he is especially careful to mention that the inflammatory infiltration disappears very quickly, and that necrosis can easily be prevented if the injections are made early enough.

It must certainly be considered a great advance, that antiparasitics began to be used in the treatment of boils, but injections are not as advantageous as might be desired, for not only are they, according to the statements of a physician in whom they were made in a hazel-nut-sized furuncle, excessively painful, but it is also not possible to use them in every part of the body. It would, for instance, not be very easy to make an injection into the scalp, and it would certainly not be pleasant for the patient were they to be made into furuncles situated in the perineum or in the ear. Even where this method could be used for single furuncles, it would not be easy to apply it if numerous nodules were present; that is, in furunculosis.

After it was shown, some years ago, that micro-organisms are the actual causes of furuncles, it is rather surprising that parasiticides have not long ago been used in the local treatment of boils. It is well known that among the numerous parasiticides, salicylic acid often does excellent service in diseases of the skin, but in furuncles it has, to my knowledge, never been used. I therefore tried to abort furuncles with salicylic acid, plaster or salve, and the result was really surprising, for it acted beautifully. The first case in which it was used was that of a young man, who, for three weeks previously had suffered from a large number of boils of different sizes at the back of the neck. In spite of numerous incisions, new nodules appeared as soon as others were cured. The man suffered such pains that he was unable to sleep, and he could not turn his head in the slightest degree without most severe pains. When I saw him first, he had about one dozen larger and smaller elevated, indurated, inflammatory nodules on the left side of the back of the neck. I prescribed locally an eight per cent. salicylic-acid plaster. ℞. Acid. salicyl., ʒ ij.; empl. saponat., ℥ ij.; empl. diachyl. s., ℥ j. When I again saw him, three days later, the pains had disappeared, he could move his head in every direction, and only a few superficial nodules remained; in three days more he was cured. I had opportunity to test the action of salicylic acid in furuncles several times, and almost every time with the best success. If applied early enough, it never took longer than six or eight days to cure furuncles of even a large size and of long duration, and the relief to the patient was manifested in a very short time. It is immaterial whether the salicylic acid is used as a salve or in the form of a plaster, the effect is always the same, and a five to ten per cent. salicylic-acid salve is of the same service. I use the officinal Unguentum aquæ rosæ as the basis for salves, not only because it has an agreeable smell, but because it is harmless, and this cannot always be said of vaseline, which is sometimes not free from sulphuric acid. A pleasant way to use the salicylic acid is in the form of the ten per cent. mull, which was first introduced by Unna; it is used in the same way as

[1] Flügge: Die Mikroorganismen, 2te Auflage, pag. 148.

[1] Berliner klinische Wochenschrift, No. 14, 1887.

the plaster, and causes a superficial formation of blisters, or a sloughing of the skin.

If, as I hope, the salicylic acid will prove as efficacious in other hands as it has in mine, we have a means to cure the furuncles every time as soon as they are formed, and, if applied early enough, necrosis will never set in. I have noticed that, if applied too late, no core will be formed, but merely an accumulation of pus, which can be treated as a common abscess. If necrosis of the tissue is once present, salicylic acid also will have no more effect, and the best thing then is to open the boil with the knife, and hasten the cure by application of the salicylic-acid salve. This treatment of furuncles is very simple, and is, I think, to be preferred to an injection. Whether this mode of treatment is also efficient in carbuncles and felons I do not know, for I have had no opportunity to use it in these. In all probability a favorable result will be seen even here, since salicylic acid first macerates the epidermis and then sloughens it, whereby it can quickly penetrate into the skin and kill the staphylococcus.

In conclusion, a few words about the general treatment of furunculosis and about the so-called furunculous diathesis. It cannot be denied that a badly nourished person or one weakened by disease offers, on account of the great irritability of the skin, a more favorable soil to the staphylococcus than a healthy individual, and an improvement of the general health, as far as it is in our power, is certainly indicated. The local treatment, however, is by all means more important in furunculosis than the general, since it gives immediate relief to the patient. I know of cases where a furunculosis, which had lasted for weeks and months, was cured by the local application of a one per cent. salicylic-acid salve. Special care must be taken that the salicylic acid is equally divided throughout the salve, and all the patient has to do is to apply it every morning and evening in a thin layer.

Family Predisposition to Fractures.—Stüdensky observed an instance of family fragility of bones. Unfortunately the details, which concern only father and seven children, are far from being complete. The number of fractures sustained by the family is upward of fifteen: 1. The father had four fractures (three of the left upper extremity and one of the femur) during the first five years of his life, while between fourteen and eighteen he broke many times his legs and arms, and that always from most trifling injuries, such as making a slip, etc. 2. The second son, at present aged twenty-seven, had six fractures (five of the left forearm, twice both the ulna and radius being broken, and one of the left humerus) during the first six years of life. All the fractures took place during some harmless plays—from slipping and falling, or from striking his arm against the table's foot, etc. His general health at the time was satisfactory, but in adolescence he suffered from extreme anæmia, while now his state is very satisfactory. 3. A fourth son, always anæmic and emaciated; at three, had a fracture of a forearm (both of the ulna and radius), from a slip on the ice; at five, a fracture of forearm from tumbling down during play; at twenty-two, a fracture of his right clavicle from slipping on an ice-glazed pavement. 4. A fifth son, always anæmic, broke one of his forearms in childhood. 5. A seventh son (weak), at five, fractured a forearm after a trifling fall when at play in the room.

Observations on a Faster.—At a recent meeting of the Berliner Medicinischer Gesellschaft, Dr. Senator reported the results of daily examinations of the excretions of Cetti, while he was undergoing one of his long fasts. No very important facts were learned from the series of observations made, but the speaker hoped to be able to repeat his examinations, and to obtain more satisfactory results.

Clinical Department.

A CASE OF ACONITE-POISONING, WITH RECOVERY.

Dr. C. C. Bradley, of this city, reports the case of a patient, age not stated, who swallowed an ounce and a half of Fleming's tincture of aconite: "After the usual symptoms of numbness and tingling of the lips and extremities, profuse sweating, cold surface, and dilated pupils, general convulsions occurred. These were three in number and epileptiform in character. Three hours after taking the dose the patient became comatose, pulseless, and devoid of sensation, respiration became stertorous and irregular, and the heart-sounds almost imperceptible. After remaining in this condition for nine hours, the circulation was gradually restored. Treatment consisted in administration of emetics, followed by brandy, ether, digitalis, ammonia carbonate, and caffeine, hypodermatically and per orem, ammonia and amyl nitrite by inhalation, and hot applications externally."

OBSTRUCTION OF THE BOWELS RELIEVED BY GASEOUS ENEMATA.

Dr. W. P. Copeland, of Eufaula, Ala., reports the following case: "A man, aged about forty, sent for one of my confrères because of severe pain in the region of the ileo-cæcal valve. On an examination, a tumor the size of a large orange was outlined in the right inguinal region, which was very sensitive and painful on manipulation. The pain was so severe that the attending physician found it necessary to give morphine hypodermatically; he also gave calomel and, later on in the day, a large dose of castor-oil, followed by enemas of water. During the early part of the succeeding night, as the patient failed to obtain relief, the pain becoming so severe as to be unendurable, I was called in, and administered another hypodermic administration of morphine, and resorted to enemas of various substances without obtaining any reduction of the tumor or movement of the bowels. On the following day, the second one of his sickness, the case looked so hopeless that we thought best to notify the family of the patient's critical condition. They telegraphed to one of the most experienced and skilful physicians in another city, for his earliest possible attendance in consultation. Late in the afternoon it occurred to me to use an enema of carbon dioxide, and, having the apparatus for generating and administering the gas near at hand, I proceeded to do so. When about one-third of the contents of the gas bag had been injected, the patient expressed a desire to go to stool, which he did, with the result of passing about half a teacupful of fæcal matter. The enema was repeated, this time being followed by a considerable passage, after which the patient had other actions without further administration, and has since been able to move his bowels as usual. Whatever doubts may occupy the medical mind as to the beneficial results of gaseous enemas, recommended by Dr. Bergeon, there is none as to its efficacy in the above case. Of course, the precautions as laid down in regard to overdistention should be carefully observed, as I have no doubt much harm might accrue from a careless use of the method."

Iodoform Pencils in Soft Chancre.—Dr. Oscar V. Petersen, of St. Petersburg, recommends, in the treatment of chancroid, pencils made of fifty or seventy per cent. of iodoform, together with glycerine and gum-arabic, and enclosed in a wooden holder. In the case of a chancroid ulcer, the pencil need only be applied to its surface, which then becomes coated with a more or less thick layer of iodoform. The chief advantage of the method is, that the patient remains absolutely free from an unpleasant and tell-tale odor.

Progress of Medical Science.

Abdominal Exploration for Chronic Intestinal Obstruction: Relief of Symptoms by Formation of an Artificial Anus and Subsequent Removal of Growth Involving Splenic Flexure of Colon.—At a recent meeting of the London Clinical Society, Dr. Pitts read a report on a case illustrating the subject of the title. The patient, Mrs. D., came under observation in St. Thomas' Hospital, on August 21, 1886. She was aged thirty-seven, and had enjoyed good health till October, 1885, when the first obstructive attack took place. For the six weeks prior to her admission, she had had no satisfactory evacuation of the bowels, even after repeated enemas. She was a thin, pale woman with distended abdomen, coils to be seen and felt, much peristaltic movement, and occasional vomiting—one large coil was especially marked, running across the abdomen from above downward toward the left groin. On examination under an anæsthetic, no tumor could be felt, and the rectum was normal. On September 21st the vomiting became continuous and offensive, and the patient was very exhausted; the vomiting was checked by morphia, but no action of the bowels could be obtained. In consultation with Mr. Edmunds, it was decided to explore the abdomen in the middle line, and this was done on September 24th; the transverse colon was greatly distended and displaced downward, and the descending colon was completely empty. The end of the transverse colon was attached to a small separate incision in the upper part of the left semilunaris, but the bowel was not opened till several days had elapsed, and the central wound had healed. The patient was in a very depressed state for the week following the opening of the colon. A very large quantity of fæces continuously passed, and she was apparently poisoned by the gases generated during the evacuation. Her breath had a strong fæcal odor, she was for days very drowsy, not recognizing her husband—fractious, and suspicious of those around her. After getting rid of the very large fæcal collection she rapidly improved, and was able to get up on November 5th; her weight was then seven stone four pounds; weight before operation, six stone ten pounds. By introducing the finger into the colotomy-opening, a movable mass about the size of a small orange could be felt under the the ribs, evidently a malignant stricture at the splenic flexure. It was therefore decided to attempt the removal of the affected bowel. After careful preliminary treatment, this secondary operation was performed on November 22d. An oblique incision was made on the left side below the ribs, about two inches above the colotomy-opening, and, by hauling on the collapsed descending colon, the affected portion of bowel was drawn out of the wound—and about four and a half inches excised; several small glands, and some adherent omentum were also taken away. The two ends of the bowel were carefully united by silk sutures throughout their posterior and lateral aspects. The muscular coat of this united part of bowel was then attached by numerous sutures to the abdominal opening, and the everted mucous membrane carefully stitched to the skin. The patient was then left in the condition of possessing a second colotomy-opening, the first opening having contracted to the size of the little finger. The patient made a rapid recovery; the temperature remained normal; and on the tenth day she was able to get up. She left for home on January 2d, wearing a vulcanite tube, with the hope that fæces might pass into the lower bowel, and the natural passage be restored. Mrs. D. was now, five months after the removal of the growth, in perfect health, and able to do ordinary household work. Her weight was nine stone, or a gain of more than two stone since the relief of the obstruction; the bowels were open regularly every morning by the second colotomy-opening, but there was complete control for the rest of the day. The specimen, a typical columnar epithelioma of the bowel, was shown and described. Mr. Pitts, in remarking on the case, gave his reasons for making the abdominal exploration, and quoted two other cases of stricture of the large bowel, in which he had made a preliminary abdominal exploration before opening the bowel at a selected position. By the exploration it was possible to gain definite information as to the cause and extent of the mischief, and this was of immense advantage when any further radical measure was contemplated. When no stricture was found in the rectum, he regarded a chance colotomy as an unsurgical procedure. In each of these cases the selected portion of the bowel had been attached to a separate opening in the abdominal wall for three reasons. 1. It allows the exploration-incision to heal by first intention, and as the second opening is exactly the size wanted, and as the bowel is stretched all round, there is no wound near the bowel-opening to heal. 2. The bowel is not displaced from its natural position by being drawn up to the central wound. 3. And most important, it is of great advantage for after-examination to have the opening near the seat of mischief, so that an after-exploration with the finger may determine the character of the stricture and its relations. At the primary exploration, when the bowels are greatly distended, it is well to be content with a very limited examination, and on no account to attempt any removal of growth until all obstructive trouble has been relieved, and the bowel has been thoroughly washed out.—*Medical Press.*

Against Bergeon's Method of Treating Diseases of the Respiratory Organs.—Dr. Wyss, of Geneva, passing in review Dr. Bergeon's new method of treating the diseases of the respiratory organs, and blood-poisoning, by means of rectal injections of gases, on which Dr. V. Morel recently published a treatise ("Nouveau Traitement des Affections des Voies respiratoires et des Intoxications du Sang par les Injections rectales gazeuses," Paris, 1886), makes the following remarks (*London Medical Record*): Every new suggestion for the treatment of tuberculosis of the lungs calls forth new hopes of having at last discovered an infallible remedy for this dire disease, and is eagerly submitted to the test both by the profession and the patients. This has always been the case, and was so again. But within the last few years Professor Rokitansky, in Innsbruck, reported on the eminent successes of his treatment of pulmonary tuberculosis with natrium benzoicum. The affected lungs cicatrized with unusual rapidity, the general condition of the patient visibly improved, the weight of the body rapidly increased, and the confidence in an ultimate complete recovery for some time seemed to become realized. But, unfortunately, only too soon the French saw that "Elle a duré ce que durent les roses" also applied to these cases. Already, after a few months, this method, like so many others, has been abandoned; not one single control and test experiment by impartial investigators bore out Rokitansky's asserted brilliant results. The question at issue in this case is: Is Dr. Bergeon's new method based on sound scientific principles, or will it be doomed to failure like that of Rokitansky and others? Only those therapeutic methods can be considered to be in accordance with the present state of medical science which are supported by the scrutinizing test of experiments. Especially in the treatment of diseases the origin of which is beyond contest of parasitic nature, previous experiments on animals are indispensable. "The degree of efficacy of any method of treatment of tuberculosis," Professor Cornil very pertinently maintains in his communication to the Académie de Médecine, "can only be corroborated by experimental investigation on animals previously rendered tuberculous. The effects of a therapeutic on microbes can only be ascertained by the most conscientious experiments on pure cultures." Dr. Bergeon's mode of treatment has not yet been borne out by this indispensable test, at least nothing is known on the subject, and the publications of Professor Cornil's

promised experiments are still expected. Dr. Bergeon's treatment, as is now well known, consists in the intimate permeation of the whole body by gaseous substances, on the supposition that these will destroy bacilli and the products of their secretions without a poisonous or otherwise injurious effect upon the patient. It is, however, doubtful whether the tubercle-bacilli and the presupposed products of their secretions be really rendered innocuous by this proceeding, which has not been proved, the less so as bacilli still continued in the sputa of patients treated according to this method after their alleged cure. The temporary improvement of the patients may have been due to exceptionally favorable hygienic or dietetic conditions. It is a well-known fact that many tuberculous patients regularly improve during the warmer season, while the changeable climate of the winter has a very injurious influence on their disease. Professor Cornil, in his communication to the Académie de Médecine, on October 19, 1886, reported on patients who had been treated after Bergeon's method during the summer months by Dr. Chantemesse, in Paris. The then undoubtedly apparent improvement may partly have been the effect of the beneficial influence of the warm weather. It is therefore necessary to have unbiassed observations on the results of Bergeon's mode of treatment during the winter. This new treatment has been tested by several physicians at Geneva, by Dr. Côrdés, Professor Dr. Vuiller, in the Cantonal Hospital, etc. Dr. Wyss watched the effects on three patients, who had long continued under his observation, and in whose expectorations he continually discovered numerous bacilli. Every one of these had borne the rectal injection of gases badly, and died within one to two months after. In one of them, a man aged forty, whose treatment Dr. Bergeon personally conducted, the injection brought on such violent colics and diarrhœas that they had to be entirely discontinued after one month. It is very questionable whether this otherwise ingeniously devised method of treatment will prove of positive therapeutic value in other infectious diseases, and in non-parasitic affections of the respiratory organs.

Jaundice in Pregnant Women.—According to Dr. Queirel (*Nouv. Archives d'Obstét. et de Gynécol.*) the condition of pregnancy affects not only the secretion, but the structure of the liver; a fact which has frequently been observed both post-mortem and clinically. The intensity of the jaundice depends upon the degree of structural change in that organ. It is also sometimes due to simple secretory irritation or congestion. Jaundice occurring early in pregnancy is rarely serious, but toward its termination the graver forms present themselves. However grave the case may be, if delivery take place the affection generally yields and disappears. On several occasions he had noticed jaundice to supervene at the very commencement of pregnancy, coinciding with the first menstrual lapsus. In none of the cases could any hepatic enlargement be made out, and it yielded to treatment. The author quotes four cases where the woman was jaundiced during the first few months of pregnancy, but where labor took place with living children at term. In the severer forms the absorption of the bile-salts is the immediate cause, and this is conduced to by the gravid alterations in the hepatic structure. He observed the case of a woman, twenty-nine years of age, in whom jaundice had lasted throughout pregnancy, becoming very intense toward its termination, yet she made a good recovery. In three other cases labor was followed by death from coma, puerperal peritonitis, and post-partum hemorrhage.

Thallin in Typhoid Fever.—Dr. Ehrlich, from further experience with the drug, concludes that the advantages of the thallin are: 1. The marked beneficial effect on the sensorium and the consequent avoidance of complications. 2. After apyresis the specific feeling of illness disappears, to make room for absolute euphoria. 3. Thallin agrees remarkably well with the stomach, some few cases of idiosyncrasy excepted, the appetite being at once good after apyresis. 4. Ehrlich assumes that thallin has a good effect on the local processes in the intestinal canal, since he never met with intestinal hemorrhage and peritonitis. 5. The largest doses do not affect the heart or kidneys unfavorably, the pulse becoming less frequent, and the traces of albumen disappearing. Perspiration occurs, but is not inconveniently great. On the other hand, thallin appears to retard retrogression of the splenic swelling, and, during convalescence, patients generally remain pale, with a feeling of lassitude. Though it does not hurt certain parenchymata, it has an unfavorable effect on the general nourishment. This may be accounted for by the fact that, like antifebrin and antipyrin, thallin causes a considerable increase of urine, partly perhaps because it causes thirst. With the hydropathic treatment death occurred chiefly during the height of the fever, while with thallin it occurred later. In the height of the disease thallin is most efficacious, warding off the peculiar dangers better than any other known remedy; while in the later period and during convalescence the hydropathic treatment is to be preferred, because it does not tax the strength of the patient as thallin does.

Prophylaxis of Croup.—The subject of the prevention of croup has been studied by Dr. Dumas for several years, and he has tried a great many substances with this object in view. The agent which he thinks best of is iodine, given internally in quantities not exceeding eight drops daily. He gives it in orange-flower water, sweetened with sirup, and adds a little iodide of potassium. He quotes a number of cases where there was every reason to suspect an attack of croup, and where the use of this remedy appeared to prevent its onset. He is anxious to see the method tried generally, so as to be enabled to arrive at a definite opinion on its merits.

A Remedy for Neuralgia.—It is claimed that a few drops of the following—eau de Cologne, ether, chloroform, ana ʒ iij.—poured on a handkerchief previously wetted with cold water, and placed on the seat of a neuralgic pain gives instantaneous relief. It is also very efficacious for nervous headache. A burning sensation is felt at first, but quickly disappears.

Tetanus Cured by Hypodermic Injections of Cocaine.—Dr. Lopez reports the following case (*London Medical Record*): M. G——, fifty years of age, after working in the wet and cold, complained of rheumatic pains of back and limbs. Three days later he had marked opisthotonous and painful cramps, and all the symptoms of idiopathic tetanus. Chloral hydrate and morphine were prescribed. For three days the patient was kept under the influences of these drugs, with the result that the pain was lessened, but the muscular rigidity and cramps increased. He now became unable to swallow, and death seemed imminent. Morphine was injected hypodermically, but was followed by no amelioration of the symptoms. Three syringefuls of the mixed solutions of the morphine and cocaine (each five per cent.) were then injected. The effect was immediate. After two hours he could move the limbs, turn in bed, and open his mouth. On the next day he was going on well; slight trismus and stiffness of the neck remained. On both sides of the neck, and at the angle of the jaw, a fourth part of the syringeful of the same solution was injected. On the next day all the symptoms had disappeared. The patient rapidly regained strength, and in a week's time returned to work.

Professor Schroeder enjoyed from his practice an income of 250,000 marks annually; Gusserow, 150,000 marks; Martin, 100,000 marks; while Waldeyer, from his teaching, realizes 25,000 marks yearly. Martin has been known to ask and receive 4,500 marks for an ovariotomy.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 6, 1887.

THE PROPHYLAXIS OF MALARIA.

IN a paper read before the Reale Accademia dei Lincei (Rome, 1887), Dr. Tommasi-Crudeli gives an excellent *résumé* of our present knowledge concerning the nature of malaria, and of the means which have been found to be most efficacious in the purification of malarious regions and in the personal prophylaxis of those living in them. Passing over for the present the first two of these subjects, we desire to direct our readers' attention to the last, namely, the measures which have been found by experience to be most effectual in preventing the symptoms of the disease in those who are exposed to malarial influences.

The methods proposed are not new, and have already been discussed more than once in these columns. Nevertheless, the subject is one of such importance, and the authority of the writer is so universally recognized, that no excuse is necessary in again referring to the matter.

The value of arsenic in the prophylaxis of malaria is well known, but it is by no means an infallible remedy. One cause of failure in certain cases is explained by the author. Arsenic owes its efficacy as a preventive remedy to its action in artificially increasing the power of the human organism to resist the aggressions of the malarial ferment. But it not infrequently fails in this effect because the natural powers of resistance are already depressed far below the normal in consequence of insufficient food, of unhealthy surroundings, or of previous malarial attacks. In such cases it has been proposed by Dr. Ricchi to administer *trefusia*, known among us as dried blood, in addition to the arsenic. The combined use of these two remedies, the author asserts, has served to preserve many from malarial attacks, who would otherwise have almost surely suffered from some of the manifestations of the poison.

Sometimes, however, this fails to afford the hoped-for protection. Such failures are met with usually in regions where the malarial poison is especially active, and are due to the fact that the natives are so impregnated with the infection that it is impossible to eliminate it by quinine, arsenic, or any of the usual remedies. In these cases the author has found the decoction of lemon to be especially serviceable. This domestic remedy, for advocating which Crudeli has suffered much ridicule, has been found by many competent observers to be of singular, and as yet unexplained, efficacy. Possibly its effects may be due, in a measure at least, to its manifest tonic properties. It certainly increases the appetite and aids digestion. As some of our readers may not remember the directions for preparing this decoction, we will repeat them here. A fresh lemon is cut into thin slices, rind as well as pulp, and is boiled in three cupfuls of water in an earthen vessel which has served no other uses. This amount is boiled down to one cupful, is then strained with pressure through linen, and set aside over night. It is then drank in the morning before breakfast. It has a slightly bitter, but not disagreeable taste, and is taken readily even by children. Such a simple and inexpensive remedy, recommended as it is by as high an authority as Tommasi-Crudeli, is well worthy of a more extended trial than it has received in this country, although it has been experimented with to some extent, we understand, in some of the Philadelphia hospitals. A hospital, however, is not the place for such an experiment, and we shall be glad to learn of its extended trial in country districts where malaria is rife. The results of such trials would be interesting, and a valuable contribution to therapeutic science.

SOME OF THE MEDICAL USES OF THYMOL.

THYMOL, as is well known, is a stearoptene obtained from the *Ptychotis Ajowan*, and in small amount also from *Thymus vulgaris*. It occurs in large transparent crystals, is soluble in eight hundred parts of water, and freely soluble in ether and alcohol. It has been employed chiefly as an antiseptic in surgery, and though used to some extent internally, its value in this respect is not as generally recognized as, perhaps, it ought to be.

It is said to be of considerable utility in catarrh of the bladder and also in diabetes mellitus, though its mode of action in this affection is not easy of explanation. It is in diarrhœa, however, that it has found its principal employment as an internal remedy. Three years ago, when the cholera was prevalent in Italy, Bozzolo endeavored to popularize the remedy by articles in the daily press, urging its general use in that disease. His recommendations were based purely on theoretical grounds, and whether they were acted upon, and, if so, what the results were, we are unable to learn. It has, however, been used to some extent in the summer diarrhœa of children, with, it is said, considerable success.

In a recent monograph by Dr. V. Martini, of Sienna, entitled "The Efficacy of Thymol in Intestinal Disinfection" (Milan, 1887), an account is given of a number of experiments with thymol in intestinal disorders, in which its utility would appear to be clearly shown. The author regards the insolubility of this substance as perhaps the one quality which renders it of peculiar value in intestinal disinfection. This quality renders it possible to exhibit the drug in large doses without fear of producing toxic effects by reason of its absorption. It passes in great measure undissolved into the intestinal canal, and there exerts locally its powerful antiseptic action. Dr. Martini reports *in extenso* nineteen cases of diarrhœa and dysentery in which thymol was used. The cases embraced chronic diarrhœa, diarrhœa from overeating, acute dysentery, the diarrhœa of phthisis, chronic dysentery, and the diarrhœa of teething children. In

almost every case a cure was obtained in from two to twelve days, the only exception being the cases of chronic dysentery, in which no good results were obtained, except that the number of the evacuations was slightly reduced. In only one case, that of a debilitated child to whom very large doses had been given, were any toxic symptoms noted. This child had some delirium and sopor. In the case of adults the author gave from twenty grains to two drachms in divided doses in the twenty-four hours.

Thymol has also been used with success as an external application in eczema and psoriasis, and especially in burns. But of these external uses we need not speak, as it was to the alleged value of thymol as an internal disinfectant that we wished especially to refer. It may, however, be worth alluding to the fact that a solution of thymol, employed in the form of a mouth-wash and gargle, is very useful in destroying the odor of tobacco which remains in the breath after smoking.

CALCIUM PHOSPHATE IN TUBERCULAR JOINT-DISEASES.

A NEW method of treatment of chronic tubercular joint-diseases has been proposed by Dr. Kolischer (*Wiener Medizinische Presse*, No. 22, 1887), which is said to have given remarkable results in the cases in which it has been tried. The author of the method was led to its adoption by a consideration of certain cases of spontaneous cure of local tuberculosis by the calcification of the morbid product, or by the intercurrence of an intense inflammation from traumatic or septic causes, as after an articular fracture. His object was therefore twofold—to obtain calcification of the tuberculous product, and to excite an inflammation which would be substitutive to the tubercular process. This object he claims to have obtained by the injection at the seat of disease of a concentrated solution of the acid phosphate of calcium.

A few experiments sufficed to show that the best results were obtained when the solution contained an excess of phosphoric acid. The solution used for injection, prepared after a formula suggested by Dr. Freund, is made as follows: 75 grains of the neutral phosphate of calcium are dissolved in 12 drachms of water, and phosphoric acid is added slowly until a perfect solution is obtained; to this are added 9 minims of dilute phosphoric acid (Austrian Pharmacopœia) and water enough to make 3 ounces. The solution is sterilized by boiling. A second solution, prepared like the first, but containing 90 or 180 instead of 9 minims of dilute phosphoric acid, is used for impregnating the gauze for dressings.

The solution is thrown at several points into the fungoid mass by means of a hard-rubber syringe armed with a platinum needle, and then a dressing of gauze impregnated with the second solution is applied. The pain, for a few hours, is very severe, and must be combated with morphine. There is some fever for a few hours, and the inflammatory reaction lasts from four to seven days. At the end of from two to four weeks considerable induration of the parts is present, but this gradually disappears in the course of a few weeks more, and the joint resumes its normal contour. In those cases in which caseation is present the skin breaks, and there is considerable discharge for a time, but the opening gradually closes if the calcium-phosphate dressing is continued, and a firm cicatrix forms.

In a letter from Vienna to *La Riforma Medica* for July 2, 1887, Dr. del Torre writes that this method has already been tried in about two hundred cases, and the results obtained have been in the highest degree satisfactory. Professor Albert has also given it his emphatic approval, and speaks of it in enthusiastic terms. There can be no question that some such method, by which the long and tedious treatment of chronic joint-diseases may be hastened, is a thing to be desired, and it is to be hoped that the activity that is now shown by surgeons in this direction may be productive of fruit in the near future, even if Kolischer's method does not come up to the high expectations of its author and his followers.

BASE-BALL PITCHER'S ARM.

DR. A. H. P. LEUF, of Philadelphia, has made an original and valuable contribution to the physiology and pathology of our national game in an article in the *Medical News* of June 16, 1887. It is fortunate for those interested in the game that Dr. Leuf is both a good ball-player and a good physician. He has given the first clear description of the physiology of pitching, and of its pathological results. The pitching of balls for amusement is an occupation which collects hundreds of thousands of Americans together during the season, and earns for the pitcher an average income considerably above that made by members of learned professions.

The work of pitching, however, is most arduous while it lasts. The ball has not only to be sent with great swiftness, but, by a peculiar jerk or snap of the forearm and hand, it is given a twist which causes it to curve in or out, up or down. Different sets of muscles are especially called into play in giving the different curves.

The *in-curve* calls into action most particularly the pectoralis major, the biceps, brachialis anticus, and flexors of the forearm. The *out-curve* affects the pectoralis major, coraco-brachialis, infraspinatus, teres minor, and ulnar muscles. The *down-curve* strains most especially the pectoralis major, trapezius, deltoid, and serratus magnus. The *up-curve* is mostly caused by the pectoralis major, biceps, and supinator brevis.

All kinds of pitching strain the elbow-joint. There is a tendency each time to a separation of the bones at the outer side of the joint—*i.e.*, radius and capitellum of the humerus. This is prevented, however, by the biceps, supinator longus, and extensor carpi radialis longior. The constant necessity for quick and forcible flexion of the elbow greatly strains the brachialis anticus; this is, therefore, one of the first among the muscles to feel the strain.

The symptoms brought on by the exercise are soreness, tenderness, myalgia, and severe, continuous, sickening pains due to involvement of the bones. There is also stiffness and weakness of the arm. These symptoms are due to the straining of the muscles and ligaments, with, probably at times, rupture of small fibres. Dr. Leuf makes the interesting observation that in cases of long standing the bones become affected, and that in pitcher's arm the trouble is largely osteitic. The ostei-

tic changes occur wherever the muscles most used have their attachment, and especially where the bone at the point of attachment is soft and porous. For this reason most trouble is encountered at the extremities of the bones. The particular change seems to be really a periostitis and osteitis, with local hypertrophy of bone.

The muscles most often or earliest affected are the brachialis anticus, lower part of the biceps, the deltoid, trapezius, and latissimus dorsi. The forearm gets tender and sore for a short time. The ligaments most affected are the coraco-humeral and coraco-clavicular, and the lateral ligaments of the elbow-joint. The wrist ligaments are sometimes affected.

The treatment consists first in prophylaxis. The pitcher must practise regularly daily in the sun. When the temperature in the shade is below 60° F., it is risky to pitch with vigor. This point is certainly often disregarded. Liniments, rubbing, and massage are all useless. The best local application is heat, which, combined with elevation of the limb, will often relieve pain. The main treatment for pitcher's arm is regular exercise, twice daily. In severer chronic cases, mild galvanic currents are of some value, and should be applied at night.

It appears from the foregoing that ball-pitcher's arm is not a rough pathological condition, but that in its severer and chronic forms it is a painful osteitis and periosteitis, combined with some ligamentous and muscular strain. The treatment is not rest, but exercise.

THE CONDITION OF THE CROWN PRINCE—CABLE MESSAGE FROM DR. MACKENZIE.

A CABLE message from Dr. Mackenzie, of London, to THE MEDICAL RECORD announces that a fourth operation upon the throat of the Crown Prince of Germany was performed on Tuesday in consequence of a recurrence of the disease. A platinum-pointed galvano-electrode was used for the purpose.

On examination of the throat immediately after the operation, an eschar was to be seen in the centre of the base of the growth. The condition of the larynx was most satisfactory, there being no inflammatory reaction, the voice being good, and the general health excellent.

The nature of the operation would preclude the possibility of any microscopical examination of the diseased tissue being made. We are thus thrown, in our estimates of final results, upon the purely clinical character of the growth. It is gratifying to infer that there has not been as yet any serious encroachment of the disease upon the tissues of the vocal cords.

In fact, thus far, everything appears to be favorable, save a marked tendency to recurrence of the disease. The latter, however, is of the greatest possible significance in estimating the probabilities regarding the ultimate malignancy of the growth. We regret to say that the outlook is not as encouraging as it might be. The best we can hope is that there will be no further disposition for the return of the growth.

THE MURIATE OF QUININE is the best salt for hypodermic use.

News of the Week.

THE FIFTH ANNUAL MEETING OF THE AMERICAN RHINOLOGICAL ASSOCIATION is to be held at Washington City, D. C., September 1st, 2d, and 3d. The profession is cordially invited to attend the sessions.

WEST VIRGINIA STATE MEDICAL SOCIETY. — The twenty-first annual meeting of the West Virginia State Medical Society was held at White Sulphur Springs, on July 13th to 15th, inclusive. There were in attendance about seventy-five members. Drs. Miles, Welch, Michael, and Opie were in attendance from Baltimore; Drs. Cullen, White, and Upshur from Richmond, Va. Thirty new members were admitted. Dr. Brock, of Morganton, was elected president for the ensuing year. The next meeting will be held at Huntington, W. Va., in May, 1888.

OUR MEDICAL COLLEGES are very busy preparing for the coming season's campaign. At the University the whole interior of the building has been torn out, and is to be remodelled, while the Loomis laboratory is rapidly approaching completion. At the Bellevue Medical College repairs and changes are going on in the Carnegie laboratory and College building itself. The new building of the College of Physicians and Surgeons, with the Sloane maternity hospital and Vanderbilt clinic, are to be ready by fall.

HUMID HEAT.—A serious danger in cities and the country from a humid atmosphere, combined with great heat, is the greater tendency for disease-germs and microorganisms of all kinds to develop. New York City in the past month has been a huge culture-plate. So far, fortunately, the death-rate from zymotic diseases has not been greatly increased. But it is to be feared that dysentery, malaria, and miasmatic troubles of various kinds will become very prevalent later.

A NEW HOSPITAL has just been opened at Camden, N. J.

A BILL WHICH PROVIDES FOR THE SUPPLYING OF ANATOMICAL MATERIAL to the medical colleges has passed the Georgia Legislature. A similar bill passed in 1879, but was vetoed by the governor.

THE MEDICAL SOCIETY OF WEST VIRGINIA has done itself credit by taking a firm stand against an attempt to mix politics up with the State Board of Health and public charitable institutions. Resolutions strongly condemning certain recent acts of the governor in this matter were unanimously adopted. We trust that some good may result. If physicians would organize and unite in action on all matters of State medicine, they would soon find that politicians would pay more attention to their opinions. At present the astute "boss" knows very well that the vote and influence of the doctors is not a thing worth bidding for.

ABDOMINAL ANEURISM CURED BY THE INTRODUCTION OF WIRE.—A case of this kind is reported by Dr. J. F. Morse, in the February issue of the *Pacific Medical and Surgical Journal*.

LONDON PROPOSES to have a Therapeutical Society. New York has proposed and tried it, but without success.

The late Dr. Joseph C. Hutchison.—At a special meeting of the Board of Managers of the Alumni Association of the Long Island College Hospital, held July 20, 1887, convened to take action in the matter of the death of Joseph C. Hutchison, M.D., LL.D., late President of the Collegiate Department, the following preamble and resolutions were adopted:

Whereas, In the death of Joseph C. Hutchison the College has lost an able worker in his recent official capacity, and one to whom it was indebted for a more active part in the past as professor of surgery, and believing the reputation and honor of the institution rests in the hands of its teachers; it is

Resolved, That one who showed such boldness and fidelity in defending its best interests is worthy of the highest praise and respect of this Association.

Resolved, That the Association extends its heartfelt sympathy to the family of the late Dr. Hutchison, and its condolence to the Board of Regents of the Long Island College in this our common affliction.

Resolved, That a copy of these resolutions be sent to the family of Dr. Hutchison, the Board of Regents, and the press.

H. Messenger Ayres,
A. H. Buckmaster,
Committee.

Cholera is said to have broken out with great violence at Catania on the island of Sicily. Twenty-five deaths occurred in one day.

Mackenzie's Fee. — Some inventive news-gatherer has started into circulation the report that Dr. Morell Mackenzie's bill for treating the Crown Prince is $13,000. Monarchies may have their faults, but it is perfectly safe to say that Dr. Mackenzie and his colleagues will be better rewarded than were the surgeons who took care of President Garfield.

Gifts to Hospitals.—Hon. Carter H. Harrison, of Chicago, has given $1,500 to the Michael Reese Hospital in that city, to be invested in its perpetual fund in the name of his late wife, Margarette Stearns Harrison.

St. Agnes' Hospital.—The Misses Drexel, of Philadelphia, have given $30,000 to St. Agnes' Hospital, with which a large lot of ground adjoining the hospital has been purchased. The property had long been desired.

How to Make Money in Physic.—Under this title an anonymous writer in the *Western Medical Reporter* publishes a long communication, which is a bold plagiarism of the well-known letter on a similar subject by the celebrated Dr. Mead. It has been in print for a hundred years, but seems applicable to-day.

International Medical Congress Railroad Rates.—The rate upon all railroads, for those designing to attend the Congress to be held at Washington in September next, has been made at one and one-third fare for the round trip, tickets to be issued on the certificate plan.

The Illinois State Medical Society.—A correspondent from Galesburg, Ill., writes: "Regarding the Illinois State Medical Society, there is but one door to that institution; no side doors nor unbarred windows, and the one door has but one door-keeper. This condition of affairs has reached such a burdensome pitch during the past five years that the profession at large, and outside of one of the Chicago medical colleges, have become very *tired*—particularly so since the caucus at New Orleans."

A Decision Against Private Hospitals.—In view of the recent discussion over the question of the unpleasant character of a certain private hospital in this city, a recent decision by Judge Hornblower in the California courts is of great interest. The case was that of the People *vs.* certain parties who were conducting a private hospital in San Francisco, known as The Hahnemann. The proprietors were charged with misdemeanor, and the charge was sustained by the judge, who said: "A private hospital must of necessity, in a populous neighborhood, be and become a public nuisance, and the people of that neighborhood have a right to protection from the courts, that they may enjoy health and happiness." The defendants were found guilty, but the case will be appealed.

Strong Galvanic Currents in the Treatment of Uterine Disease.—As a good deal has been said in regard to and in favor of Apostoli's method of treating uterine fibroids, etc., it may be well to hear the views of Dr. A. Tripier on the matter, as expressed to Dr. Julius Althaus, in the *British Medical Journal:* "More than twenty years ago M. Tripier had treated uterine fibroma with faradization, and thereby given not only considerable relief to subjective symptoms, but also obtained the dispersion of the peri-uterine engorgement which is often present in these cases, without, however, reducing the tumors. Later on he likewise made use of positive and negative electrolysis, but without any very positive results. Finding that about the latter date Apostoli was inclined to further investigate the subject, he advised him to use a current of moderate power, and for a considerable length of time, and to cover the electrodes with a protecting substance. Apostoli, however, went entirely the opposite way to work, for he used a current strength of enormous power, up to two hundred and fifty milliampères, and that for a very short time only. In this manner he obtained energetic cauterization, but left the question whether the effects produced were owing to the action of the current, or simply to the sore which was established, unsettled. He has, however, established the fact that the uterus may swallow an enormous dose of electricity for a short time, and that large fibromas may be by this proceeding considerably reduced in size in a few months. It is true that this is brought about at the price of considerable suffering to the patient, and of risks which M. Tripier would not be disposed to run. With regard to chronic metritis, M. Tripier considers M. Apostoli's proceeding to be much inferior to his own, as it leads to the formation of cicatrices. For endometritis Tripier prefers his iodine injections; for simple engorgement, faradization; and for fibrous hypertrophy, again injections. Finally, M. Tripier does not believe in the distinction which Apostoli has drawn between positive electrolysis, which is said to be hæmostatic, and negative, which is declared to be hemorrhagic. In several cases which he has seen, negative electrolysis has proved rather hæmostatic than hemorrhagic."

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Long Branch, N. J., July 20, 21, and 22, 1887.

WEDNESDAY, JULY 20TH—FIRST DAY—MORNING SESSION.

THE Association convened at the West End Hotel, and was called to order at 11.30 A.M., by the retiring President, DR. CHARLES K. MILLS, of Philadelphia.

Present.—Drs. C. K. Mills, of Philadelphia; L. C. Gray, of Brooklyn; R. T. Edes, of Washington; J. J. Putnam, of Boston; G. M. Hammond (Secretary), of New York; James Henrie Lloyd and Francis X. Dercum, of Philadelphia; E. C. Spitzka, G. W. Jacoby, B. Sachs, and R. W. Amidon, of New York.

NEW MEMBERS.

The Council reported favorably to the election of the following applicants: Drs. Henry Hun, of Albany; Henry M. Lyman, of Chicago; Irvine C. Rosse, of Washington; Theodore H. Kellogg and N. E. Brill, of of New York; and Philip C. Knapp, of Boston.

MEMBERS BY INVITATION.

Professor J. Jastrow, of Johns Hopkins University, Baltimore, and Dr. Samuel Ayers, of Pittsburg, Pa.

DR. MILLS then delivered

THE ADDRESS OF THE RETIRING PRESIDENT,

in which he recommended the adoption of certain proposed amendments to the constitution and by-laws, and briefly referred to the proposition to join the Congress of American Physicians and Surgeons. He closed his address with a reference to the subject of "Arrested and Aberrant Development of Fissures and Gyri of the Brain," brought forward in his address last year, and then read a letter from Professor Benedikt, of Vienna, to whose work in connection with the subject of the "Brains of Criminals" he had directed attention.

At the close of his address he introduced DR. LANDON CARTER GRAY, of Brooklyn, N. Y., who then delivered

THE ADDRESS OF THE PRESIDENT-ELECT,

in which he departed from the somewhat established custom of presenting a paper on a subject connected with the scientific work of the Association, and gave a brief *résumé* of the history and present status of neurological science as represented by neurological societies in Europe and in this country. The first neurological society (New York) in this country was organized in 1872, and the American Neurological Association began its existence in 1875. Three years ago the Philadelphia Neurological Society was organized.

With all its prestige and intrinsic advantages, Europe has only three special neurological societies, as against three in this country, established within fifteen years.

The President then reviewed the work which had been done by neurologists, and expressed himself as having but little sympathy with the attacks being made on specialism. Neurology had made within the last quarter of a century astonishing strides, which were illustrated in the advancements made in cortical localization, insanity, locomotor ataxy, multiple neuritis, athetosis, and many other diseases, as well as by the means of study. These justly entitled it to be placed in a position which rendered a thorough knowledge of the phenomena of the nervous system a necessity for the general practitioner, if he would be most competent to practise medicine.

In conclusion, he expressed the hope that the Association would become an integral part of

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

The first paper was read by DR. E. C. SPITZKA, of New York, on

SOME POINTS REGARDING THERAPEUTICAL AND OTHER INJURIES OF THE BRAIN.

The observations were made while experimenting on animals for purposes other than those set forth in the paper. They varied from the excision of entire hemispheres and simple trephining and the introduction of foreign substances into the arachnoid cavity to the injection of such substances into the brain-tissue directly, into the ventricular cavities, and into the arachnoid sacs at the base of the brain. Terebration or trephining necessarily preceded the introduction of hypodermic needles in the latter instances. It was also his fortune to witness one extensive operative exposure of the human brain, and to make the post-mortem analysis in two cases where operations had been attempted or made in accordance with the modern teachings of cerebral surgery.

He concludes that, so long as the brain-axis is not injured in special provinces, practically an unlimited amount of brain-tissue can, under antizymotic precautions, be removed without compromising life; that hypodermic needles can be thrust into the brain without harm; that the button of bone removed by trephining can with safety be reinserted and left to unite.

Exploratory needles, however, should never be introduced into the internal capsule, the contiguous ganglia, or the lateral ventricles, merely for exploratory purposes, unaided by positive clinical indications of the location of disease.

Exposures of large surfaces of brain are not feasible in persons with feeble vascular walls, owing to the danger of intra-cerebral hemorrhage.

Buttons of bone reinserted under antiseptic precautions, after trephining, are, even in the event of non-union, entirely harmless.

In young persons buttons of bone may become reunited with the cranium, even though perfect coaptation be not assured.

The paper was discussed by Dr. G. M. Hammond, of New York, Drs. J. H. Lloyd and C. K. Mills, of Philadelphia, and the discussion was closed by Dr. Spitzka.

DR. JAMES J. PUTNAM, of Boston, then presented specimens and reported two cases. The first was one of

DISTROPHY OF FACE AND HEAD.

It was a case of general hyperostosis of the cranium, occurring in the person of a Swedish woman, twenty-nine years of age, and in good health up to nine years ago. There was no reason to suspect the presence of syphilis. Soon after the birth of her first child, nine years since, she began to suffer from severe headaches, and headache was a prominent symptom throughout. About two years afterward, broadening of the face and protrusion of the eyes began to be noticed, steadily increased, and became very prominent. Three years ago some of her teeth fell out, and finally all were lost. Purulent discharge from both ears appeared two years ago, and the patient became entirely deaf. Five years ago menstruation disappeared. Dizziness, accompanied by slightly tottering gait. Intelligence remained good. Sensibility of the skin normal. No evidence of paralysis of any of the ocular muscles. No optic neuritis, but dense opacity in a part of the cortical portion of the lens of the left eye, on the side where there was the greatest degree of exophthalmos.

The circumference of the head was 59 ctm., and its breadth 16 ctm., at the last measurement.

Photographs showing the increased size of the head and the protrusion of the eyes were exhibited.

Such cases had been described by Foerster, and in the museum of the Harvard medical school was a skull

which showed thickening to the extent of one and a half inches, with narrowing of all the cavities, particularly the orbital.

The second case was one of

INTRA-CRANIAL TUMOR,

occurring in a woman thirty-eight years old, who, without family history bearing on the case, suffered from periodical headaches. Eighteen months before Dr. Putnam made his examination these headaches increased in frequency, but otherwise their character remained unchanged. The whole duration of the sickness was about twenty-one months, but no symptoms unequivocally due to the disease were noticed until about four and a half months before death, the first being a terrific headache that lasted two days, and ushered in an almost unbroken series, mainly frontal. Vision was slightly indistinct, and well-marked optic neuritis was present. There were no localizing symptoms of cerebral disease. The mental condition was good. For six weeks before death she was nearly unconscious, with her right hand constantly at her head, and the power of conversation became more and more limited. When conscious she complained a great deal of pain in the two middle fingers of the left hand, running upward to the elbow. There was paresis of the buccal muscles of the right side of the face, with slight deviation of the tongue to the right. The pulse varied in frequency, and the temperature remained normal. The autopsy revealed a cerebral tumor, the outer aud upper part of which was a cyst filled with blood and detritus, occupying the position of the caudal extremity of the second and third left frontal convolutions; the remainder of the tumor was much firmer and was situated mainly beneath the frontal lobe, reaching toward the median line so far as to push the left olfactory nerve somewhat to one side. The only attachment of the tumor was to the dura, covering the left wing of the sphenoid over a space somewhat larger than a nickel-cent. The third frontal convolution in particular was thinned and softened. Except by the cerebral arteries there was no connection between the tumor and the brain. Dr. Putnam suggested the propriety of a surgical operation for the removal of the growth in such cases.

The second case was discussed by Dr. Spitzka of New York, and the discussion was closed by Dr. Putnam, after which the Association went into executive session.

AFTERNOON SESSION.

The Association was called to order by the President, DR. GRAY, when, on motion by DR. E. C. SPITZKA, of New York, the by-laws were suspended, and the Association elected William A. Hammond, of New York,

AN HONORARY MEMBER,

his name having been presented in the morning session by Dr. Charles K. Mills, of Philadelphia.

DR. C. L. DANA, of New York, then read a paper on

HEREDITARY TREMOR,

an affection heretofore undescribed.

DR. J. J. PUTMAN, of Boston, had seen such cases occurring in families in which there was no other disease. An example lived in his vicinity, who also had tremor of the head, as did the patients in some of Dr. Dana's cases, but which was not senile.

DR. G. M. HAMMOND, of New York, mentioned a case of choreaic tremor which certainly was hereditary, and he asked Dr. Dana if he regarded the form of tremor he had described the only hereditary variety.

DR. DANA recalled Dr. Hammond's case, which he had opportunity to see, but he was not aware it was hereditary, and had regarded it as one of tic convulsif rather than of tremor. The peculiarity of the cases he had described was their marked hereditary character.

DR. GEORGE W. JACOBY, of New York, then read a paper in which he gave the results of microscopical studies in a case of

PSEUDO-HYPERTROPHIC PARALYSIS.

The case occurred in a boy, fifteen years of age, who presented the usual symptoms of the disease. He obtained the privilege of removing portions of the muscles, and the results of his study had been to sustain the view that the disease is primarily myopathic. The following changes were observed: The number of bundle-fibres was reduced, at least one-half, and the size of single muscle-fibres was smaller than normal. The connective tissue was augmented to two or three times that of normal muscles. Whence comes this increase, was a question that had not been answered satisfactorily. All his specimens, however, went far to show that it had grown at the expense of the contractile substance, and that the medullary corpuscles had developed new connective tissue. Exceptionally, fat-cells were found in muscle-fibres. There were fat-cells in the new connective tissue, besides formations in the perimysium, cartilaginous in character.

His conclusions were that in his patient the disease was essentially a chronic inflammation, invading both the perimysium and the muscle-tissue. The pathological process, whatever its cause may be, consisted in a gradual reduction of the muscle-fibres into medullary or inflammatory corpuscles, which in turn go to build partly fibrous, partly cartilaginous, and partly fat connective tissue. The process, which is extremely slow, gradually leads to an augmentation of myomatous or other varieties of connective tissue at the expense of the muscle-tissue. He does not agree with Gowers and Buss that the proliferation of connective tissue is the primary, and the disease of the muscular tissue the secondary process. Either the reverse is true or the process occurs simultaneously both in the muscle and in the perimysium. Dr. Jacoby does not hesitate to place the entire process, as seen in his specimens, in the same category with the process termed *myositis ossificans progressiva.*

DR. DERCUM, of Philadelphia, had seen cases of interstitial myositis and also of myositis proper, but whether the connective-tissue change was secondary or not was difficult to say. In Dr. Jacoby's case there did not seem to be much doubt.

DR. J. J. PUTNAM, of Boston, cited cases in which a mixture of the degenerative processes occurred.

DR. B. SACHS, of New York, then read a paper on

ARRESTED CEREBRAL DEVELOPMENT,

with special reference to its pathology. The child, whose brain he had examined with the assistance of Dr. Ira Van Gieson, was two years old, with absolute lack of mental development, and without any evidence of either syphilis or rachitis. There was a distinct history of traumatism. Examination of the brain showed that the fissures were very much like those of the low type of brain illustrated in Dr. Mills' paper, read before the association last year. The island of Reil was completely exposed. The microscopical examination pertained to the cortex of the brain, and the most characteristic changes concerned the large and small pyramid-cells. Scarcely a single pyramid-cell in the entire cortex presented a normal appearance; the majority of them looked like mere clumps. Their number was notably diminished. The nucleus was entirely absent in many, and in others it was small and surrounded by detritus. The processes were either poorly developed or entirely absent.

There were no changes affecting the glia, the blood-vessels, the white fibres, or the neuroglia. There was no indication of an inflammatory process, and for that reason he regarded the case as one of pure inhibited development, and not arrest of development from previous inflammatory conditions.

The paper was discussed by Drs. Mills and Dercum, of Philadelphia, and Amidon, of New York.

The Society then went into executive session.

THURSDAY, JULY 21ST—SECOND DAY—MORNING SESSION.

The Association was called to order by THE PRESIDENT.

There were present during the day, Drs. Gray, Hammond, Miles, Putnam, Edes, Hun, Dercum, Lloyd, Jacoby, Mills, Starr, Sinkler, Sachs, Ott, Spitzka, Brill, Dana and Jastrow.

DR. J. J. PUTNAM, of Boston, reported a case of

SARCOMA INVOLVING THE INTRA-PELVIC NERVES.

It was a contribution to the clinical and pathological history of "paraplegia dolorosa," due to the invasion of the intra-abdominal nerves. The facts observed harmonized fully with those reported in the recent excellent summary and analysis by Dr. R. W. Amidon, of New York; but he regarded the case as worthy of record because of the very late appearance of anything that could be called cachexia, or of enlargement of the lymphatic glands; because of the secondary and indirect involvement of the spinal cord; and because of the very notable fluctuation of some of the symptoms. The patient was a man seventy-two years of age, of excellent previous history and habits, and no family tendency which could be expected to make him liable to sarcomatous disease. The first symptoms showed themselves about one year and a half before his death, and consisted of pain in the middle toe of the left foot, recurring frequently for some months, and occasionally throughout the remainder of his life. Although a bilateral distribution of the symptoms is usually so early and valuable a guide, the right leg in this case was not attacked until nearly six months after the left. Meantime the pain in the left had greatly lessened during a trip to Florida. No glandular enlargements could be detected until about two months before death, when a bunch was noticed in the right groin that rapidly increased in size. The new growth finally invaded the skin.

The paper was discussed by Dr. C. K. Mills, of Philadelphia, and Dr. F. T. Mills, of Baltimore, both reporting similar cases of malignant disease.

DR. JAMES HENDRIE LLOYD, of Philadelphia, then read a paper in which he reported one of a number of cases of

INSANITY OF DOUBT,

which he had seen. They are characterized by a special form of delusions which differs from the delusions of grandeur or persecution. The delusions of doubt are changeable and negative, and somewhat allied to those of melancholia. It is a species of reasoning mania. If one spirit of doubt is removed a dozen rush in to take its place. The affection belongs to the neurotic type.

The paper was discussed by Dr. C. K. Mills, of Philadelphia; Dr. L. C. Gray, of Brooklyn; and the discussion was closed by Dr. Lloyd.

The President, DR. L. C. GRAY, of Brooklyn, then read a paper on

CHOREA,

in which he argued that this disease is not so trivial an affection as it is generally supposed to be. After giving an analysis of 134 cases, which showed a large percentage of relapses, and mentioning the fact that it is a developmental disease, liable to be transformed from an apparently harmless one into a violent and dangerous affection, he cited five classes of cases which especially should be observed seriously: (1) Cases with convulsive phenomena; (2) cases with spasmodic contraction of the muscles of respiration; (3) cases with marked hysterical symptoms; (4) cases with rapid pulse or dyspnœa, without evident pulmonary or cardiac lesions; and (5) cases with cardiac and pulmonary lesions.

In the treatment he regards *rest* as the *sine qua non*—absolute rest in bed. He has not much confidence in the efficacy of arsenic to effect a permanent cure. There is danger, however, in using it in very large doses. Iron he uses as a very valuable remedy—large doses of the dialyzed. Galvanism to the spinal cord in chronic cases is usually of great service. He has not used hyoscyamine except where the bromides failed. A radical change of air is especially valuable. The paper was discussed by Dr. Starr, of New York; Dr. Lloyd, of Philadelphia; Dr. Miles, of Baltimore; Dr. Dercum, of Philadelphia; Dr. Jacoby, of New York; Dr. Hammond, of New York; Dr. Sinkler, of Philadelphia; Dr. Edes, of Washington—who reported severe cases, some fatal, some complicated with epilepsy, insanity, pregnancy, etc., and also mentioned other drugs than those referred to by Dr. Gray which they had found efficacious in the treatment of the disease.

DR. M. ALLEN STARR, of New York, then exhibited some specimens which showed the advantages of Weigert's staining for nerve-tissue.

The Association then went into executive session.

AFTERNOON SESSION.

DR. FRANCIS X. DERCUM, of Philadelphia, read a paper in which he reported two cases of

HEMICHOREA ASSOCIATED WITH BRIGHT'S DISEASE.

How shall we explain these cases? Is there a causal relation between Bright's disease and the hemichorea, or is the association of the two affections merely accidental? While he did not pretend to give a positive or final answer to the questions, he maintained that the weight of evidence was in favor of the first hypothesis. In the first place, there were no evidences of organic cerebral disease, such as were to be expected from the researches of Weir Mitchell and, later, from the work of Charcot and Raymond. There was, in these cases which he reported, no history of a previous hemiplegia, and, secondly, the autopsy of Case I. proved the entire absence of any focal lesion, while the most detailed and careful study of Case II. likewise negatived any hypothesis of organic disease.

It might seem strange, indeed, that if the chorea was really related to the Bright's disease it should be so limited in its distribution. It might be difficult to understand why a general cause should give rise to such a localized set of nervous phenomena, and yet, that disturbances of the nervous system strictly limited to one-half of the body do occur in Bright's disease was no longer a matter of doubt. The one-sided action of the nervous system in uræmia is by no means limited to old persons. DR. EDES, of Washington, was inclined to regard the association of the two diseases as accidental, and DR. MILLS, of Philadelphia, was strongly inclined to the same opinion.

DR. E. C. SPITZKA, of New York, then read a paper on

ACUTE OR GRAVE DELIRIUM,

first recognized by DR. LUTHER BELL, of Massachusetts. Ordinarily it begins with insomnia, malaise, and inability to think, accompanied by a bursting sense of pressure in the head, increasing irritability, and the sense of impending misfortune. The outbreak is often so sudden as to suggest the fulminating type of typhus or of epidemic meningitis. In such cases the patient, rising from a confused sleep, staggers around as if drunk, or, having lain down oppressed by some real grief or subjective melancholy, he or she rises hilarious, dances around, vociferates, indulges in erotic or expansive imagery, to pass into apathy, either with or without the intervention of lucid intermission. Soon the flight of ideas increases—in some a wild, aggressive delirium, in others a distress-

ing anxiety which deepens and becomes a panphobic delirium. The more violent class pray, sing, whistle, yell, and tear off their clothing continuously for days. Those who early suffer from impaired consciousness exhibit a suffused, stupid face, and lie almost motionless, groaning, or puffing and blowing with their mouths in a peculiar manner.

The findings in the brain vary from the negative to the most profound structural changes. These cases seem to illustrate the fact that any multiple irritative lesion, suddenly overwhelming the brain-function, can produce delirium and coma. All the changes, in his opinion, were the collateral results of hyperæmia, which is the characteristic of the disturbed brain-circulation, and throw no direct light on the essential pathological foundation of grave delirium. He suggested that attention should be directed to the very important question of the ability of the predisposed and overburdened nervous centres to poison themselves.

The paper was discussed by Dr. Gray, of Brooklyn, who had seen two cases like those described by Dr. Spitzka, except that they were not fatal, and by Dr. Mills, of Philadelphia, who had seen cases belonging to this category in which recovery took place. He also spoke of the difficulty of drawing the line between grave or typho-mania and the cases of common acute mania and other affections.

Dr. Spitzka, in closing the discussion, said that while in theory he was opposed to mechanical restraint in the treatment of the insane, he would find it difficult to get along without such restraint in cases of this kind, as chemical restraint fails when used in a form that would be justifiable.

Dr. Henry Hun, of Albany, read a paper entitled

GLIOMATOUS HYPERTROPHY OF THE PONS.

The patient was a girl, six years of age, who showed steadily increasing inco ordination of movements, bulbar paralysis, and general motor paresis. At the autopsy the pons was found enlarged to three or four times its natural size by a tumor, which occupied it almost completely and was glio-sarcomatous in character. He preferred the title, however, of gliomatous hypertrophy of the pons.

The paper was discussed by Drs. Starr and Spitzka, of New York.

Dr. M. Allen Starr, of New York, read a paper on

PARAMYOCLONUS MULTIPLEX,

in which he reported a case. This is a spasmodic affection of the muscular system of peculiar character, distribution, and course, dependent upon irritation of the nervous motor mechanism. It is limited to the muscles of the body and proximal portion of the limbs, only occasionally affecting the neck and face, and was first described by Friedreich. His case brings the total number up to nine. It must be regarded as a distinct disease, since it is widely different from chorea, hysterical spasms, epileptiform convulsions, convulsive tremor, or tetanilla, and tic convulsif. Its causation is uncertain. The spasms are bilateral and symmetrical. They are limited to certain muscles of a physiological group. The usual limitation of the spasm to the body-muscles, with those of the thighs and arms, is very noticeable. The character of the spasm is characteristic. It is a rapidly repeated clonic spasm, occurring at intervals, varying from fifty to one hundred and eighty per minute. The clonic contractions continue, when once set up, for a varying time from half a minute to ten minutes, and are succeeded by a complete interval of freedom from spasm. In the majority of cases, any tapping of the tendons or any irritation of the skin was sufficient to produce a spasm. This is an important diagnostic symptom. In none of the cases has consciousness, motion, sensation, co-ordination, or electric excitability been in any way affected—an important negative fact. It is a functional neurosis.

Prognosis is favorable, although relapses may occur. The treatment which has been most serviceable has been the strong galvanic current to the spine and neck, and the application of the anode to sensitive points, in case they exist. The exact effect of nerve-sedatives and nerve-tonics seems to be doubtful. The hypodermatic use of arsenic under the conditions described by Hammond deserves a trial.

The paper was discussed by Drs. Spitzka, C. L. Dana, and G. W. Jacoby, of New York, who added cases and commented on the question of differential diagnosis; by F. X. Dercum and C. K. Mills, of Philadelphia, who agreed with the other gentlemen with regard to the propriety of making this symptom-group a permanent affection; they saw no good reason for separating it from convulsive tremor, or from some affections called hysterical.

Dr. Sachs, of New York, supported Dr. Starr, and Dr. Sinkler, of Philadelphia, had seen a number of cases of convulsive tremor which closely corresponded to the description given by Dr. Starr and others, of paramyoclonus multiplex.

The discussion was closed by Dr. Starr.

The Society then went into executive session.

The annual dinner was served in the evening.

Friday, July 22d—Third Day—Final Session.

The Society was called to order by The President.

Present: Drs. Edes, Putnam, Spitzka, Hammond, Starr, Brill, Dana, Parsons, Jacoby, Ott, Dercum, Hun, Miles, Gray, Lloyd, Fisher, Mills, Kellogg, and Jastrow.

The first paper was read by Dr. Isaac Ott, of Easton, Pa., on

THE THERMOGENETIC APPARATUS.

Testimony now is in favor of the theory of spinal heat-centres. Atropia was used in his experiments on cats and rabbits, and the conclusion reached that atropia increases temperature by stimulation of the thermogenetic centres in the spinal cord. He believed that the phenomena of tetanus substantiated this view.

Dr. Spitzka, of New York, referred to Dr. Kinnicutt's paper, in which the temperature, in a case of chorea in an adult, averaged 104° F., and at times rose to 107° F., with no reason for it except muscular working. He had seen a fatal case of chorea in which the temperature reached 103° F.

Dr. C. L. Dana, of New York, read a paper in which he reported a case of

ANENCEPHALY ILLUSTRATING THE SENSORY TRACT.

The cerebral hemispheres and the corpora striata were entirely absent, while the cerebellum, pons, medulla, and optic thalami were present. There was absence of the motor tracts, while the sensory tracts were present and could be traced as far as the optic thalami. Microscopic sections and drawings were shown. Some peculiarities in the spinal cord were noted.

The paper was discussed by Drs. Starr and Spitzka, of New York.

Dr. George W. Jacoby, of New York, then read a paper (to appear in full in The Medical Record) on

THE TREATMENT OF NEURALGIA BY MEANS OF INTENSE COLD.

Dr. R. T. Edes, of Washington, referred to the use of rhigolene, as also did Dr. Dana, of New York, who had found that it produced relief in some cases for a long time, but that large quantities were required. He could confirm the value of the use of cold in the treatment of pain.

Dr. Jacoby had used rhigolene, but found it objectionable because it could not be applied to a sufficiently large surface, and because of the less degree of cold produced as compared with that obtained by the other agents.

Dr. Charles K. Mills, of Philadelphia, read a paper entitled

REMARKS ON POLIO-MYELITIS AND MULTIPLE NEURITIS OF SYPHILITIC ORIGIN.

He reported three cases which had a distinct syphilitic origin—two without other associated history, and one with the history of traumatism. The clinical phenomena in these cases corresponded very closely with those given by Dr. Starr, of New York, in his Middleton Goldsmith Lectures on multiple neuritis, and the question arose whether the symptoms were due to myelitis or to multiple neuritis, or to both.

According to his view, there are at present no clear diagnostic points between these affections which will enable one to say that, of certain cases, this is one of multiple neuritis, and that of diffuse myelitis or polio-myelitis anterior. Dr. Mills believed it to be fallacious: (1) To hold that because cases get well they are multiple neuritis, and not polio-myelitis or some other form of myelitis; (2) that because of marked sensory symptoms the case commonly is one of multiple neuritis; and (3) that because of gradual onset the case is one of myelitis, and not multiple neuritis.

The presence of positive, limited tenderness over certain nerve-trunks and the absence of paralysis of the sphincters give rise to the likelihood, in most cases, of the presence of multiple neuritis. But the symmetrical affection of physiologically related muscles, he thought, could not be relied upon to distinguish between the two diseases, and he was positive that he had seen a number of cases of multiple neuritis that were distinctly syphilitic.

The paper was discussed by Dr. Miles, of Baltimore, who believed that there were cases in which the differential diagnosis between central and peripheral paralysis could not be made; by Dr. R. T. Edes, of Washington, who thought that Dr. Mills was correct in his assumption that the two affections could coexist, but he did not feel quite certain that one was not secondary to the other in such cases.

The discussion was continued by Dr. Lloyd, of Philadelphia; by Dr. Putnam, of Boston; by Dr. Starr, Dr. Spitzka, and Dr. Dana, of New York; and the discussion was closed by Dr. Mills.

Dr. E. D. Fisher, of New York, read a paper in which he reported a case of

BULBAR PARALYSIS

that had been under his observation throughout its entire course of one and a half year. There was paralysis of the tongue and, to a milder degree, of the lower lip. The only cause ascertained was anxiety and grief. The microscopical examination revealed almost entire disappearance of the hypoglossal nuclei, and atrophy of the nerves themselves.

Dr. G. M. Hammond, of New York, mentioned a case that had a duration of six years.

Dr. Theodore H. Kellogg, of New York, read a paper on

HYDROTHERAPY IN MENTAL DISEASE.

The use of water as a therapeutical measure may be guided by the following principles:

First—careful physiological experiments have proved the effects of hot and cold water on respiration and circulation, bodily temperature, the increase of oxygenation and carbonic acid, the conversion of fat, and changes in nitrogenous tissues.

Second—rational hydrotherapeutics in mental as in other diseases must consist in the application of those physiological facts to meet symptomatic indications in accordance with the etiology and pathology of each individual case.

The indications for hydrotherapy in mental diseases are to control bodily temperature, to stimulate local and general circulation, to produce diaphoresis, to improve general nutrition, to allay irritability of peripheral nerves, to procure sleep and relieve cerebral anæmia and hyperæmia; and, in a measure, to take the place of drugs.

Dr. Ralph L. Parsons, of New York, spoke favorably of water as a therapeutic measure in the treatment of mental diseases, also of the caution which should be used with shower and other baths.

Dr. Mills, of Philadelphia, spoke of the favorable effects produced by the judicious use of this measure.

PAPERS READ BY TITLE.

The following papers were read by title: "The Treatment of Progressive Locomotor Ataxia with Rarefied Air," by H. M. Lyman, M.D., of Chicago; "Hemiplegia in Childhood," by Philip Coombs Knapp, M.D., of Boston; "Illustration of Error in Diagnosis of Some Nervous Diseases," by Irvine C. Rosse, M.D., of Washington; "On the Anatomical and Physiological Relations of the Tract usually Designated as the Column of Goll," by Nathan E. Brill, M.D., of New York.

The Association adjourned, to meet at the call of the Council.

MISCELLANEOUS BUSINESS.

The Treasurer's report showed a balance in the treasury of $110.

Amendments to the Constitution and By-Laws were adopted which provided for two Vice-Presidents (instead of one); that nominations for officers shall be made on the second day of the annual meeting (instead of the first); that the officers shall enter upon their duties immediately after they are elected; and that the membership be increased from fifty to one hundred.

The Secretary presented a number of documents received from Professor Camillo Golgi, honorary member, and also a volume of the "Transactions of the Rhode Island Medical Society."

The thanks of the Association were given to the donors, and the documents placed in the custody of the Secretary.

Drs J. J. Putnam, of Boston, G. M. Hammond and B. Sachs, of New York, were appointed by the President as a Committee on Revision of the Constitution and By-Laws and List of Members.

The President also appointed the following memorial committees: On the death of Dr. J. S. Jewell, of Chicago—Dr. Charles K. Mills, of Philadelphia, and Dr. Robert T. Edes, of Washington; on the death of Dr. Thomas A. McBride, of New York—Dr. E. C. Spitzka, of New York, and, as an intimate friend of the deceased, he (the President) claimed for himself the privilege of serving on the committee with Dr. Spitzka.

The Association voted to become an integral part of the American Congress of Physicians and Surgeons, and Dr. Landon Carter Gray, of Brooklyn, was appointed delegate, with Dr. Charles K. Mills, of Philadelphia, as alternate, to attend the meeting of the Conference Committee to be held in Washington in September next.

The Committee on Encephalic Nomenclature was continued, with the addition of Dr. E. C. Seguin, of New York, to fill the vacancy caused by the death of Dr. McBride.

OFFICERS FOR THE ENSUING YEAR.

President—J. J. Putnam, M.D., of Boston.

Vice-Presidents—Wharton Sinkler, M. D., of Philadelphia, and B. Sachs, M.D., of New York.

Secretary and Treasurer—Graeme M. Hammond, M.D., of New York.

Councillors—George W. Jacoby, M.D., of New York, and Robert T. Edes, M.D., of Washington.

A Valuable Gift.—The widow of the late Dr. Alfred Meadows has presented the library of this distinguished gynecologist to the British Gynecological Society.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-third Annual Meeting, held at the Pe uot House, New London, Conn., on Wednesday and Thursday, July 20 and 21, 1887.

WEDNESDAY, JULY 20TH—FIRST DAY—MORNING SESSION.

THE meeting was called to order by the President, DR. WILLIAM F. NORRIS, of Philadelphia.

Under the head of unfinished business the following were elected to membership: Drs. J. B. Emerson, New York; H. F. Hansell, Philadelphia; J. O. Tansley, New York; M. Haywood Post, St. Louis; and Edmund C. Rivers, Denver, Col.

A memoir of Dr. Ezra Dyer, of Newport, R. I., one of the founders of the Society, was read by DR. HASKET DERBY, of Boston, and referred to the Publication Committee.

The death of Dr. William S. Little, of Philadelphia, was also reported.

DR. C. S. BULL, of New York, presented a

REPORT OF THIRTY-SIX CASES OF SIMPLE EXTRACTION OF CATARACT WITHOUT IRIDECTOMY.

Twenty of these 36 cases were males and 16 females. In 24 the cataract was hard and senile; in 11 it was traumatic and soft or semi soft; and in 1 case it was of secondary origin. Careful antiseptic precautions were adopted in all the operations. The operation was done with the patient lying in the bed he was to occupy after operation. The knife was long, and narrower than that of Von Graefe. It was quickly passed across the anterior chamber, the flap measuring about two-fifths of the corneal circumference. Prolapse of the iris did not usually occur, but if it did, it was allowed to remain until the extrusion of the lens. The capsule was then opened by a quadrilateral incision, and by pressure the lens was caused to pass out of the corneal wound. If reduction of the iris did not occur spontaneously, it was reduced with a spatula. All soft lens-matter was washed out with the antiseptic solution and one drop of a solution of eserine instilled, of the strength of one grain to the ounce of a saturated solution of boracic acid. The lids were then closed and an antiseptic dressing applied. If the eye did well the bandage was not removed for two days, but the eserine solution was instilled twice daily under the bandage. At the end of two days the bandage was removed and the eye washed. The lids were not opened for four days, unless there was some indication for it. If at the end of this time the appearance was favorable, eserine was reinstilled and the bandage applied for another day, when it was removed altogether. The healing process was usually favorable. There was no suppuration in any case. The average duration of the treatment was a little more than twenty days. A secondary operation—usually a needling or a laceration of the posterior capsule—was required in 12 cases. Prolapse of the vitreous occurred in 4 cases, and dislocation of the lens downward in 2 cases. Eserine was not used after the healing of the cornea. The degree of acuteness of vision obtained was as follows: $\frac{20}{xxx}$, in 2 cases; $\frac{20}{xl}$, in 8 cases; $\frac{20}{1}$, in 8 cases; $\frac{20}{lxx}$, in 10 cases; $\frac{20}{cc}$, in 5 cases; and $\frac{20}{cc}$, in 2 cases.

DR. H. KNAPP, of New York: During the past year I have performed this operation 68 times. Following the operation there was mild iritis in 3 cases; severe iritis, with closure of the pupil, in 1 case; protrusion of the iris in 3 cases; incarceration of the iris, without protrusion, in 2 cases; capsulo-iritis in 1 case; and suppuration in 1 case—this was secondary to an old disease of the eye. In 27 cases a secondary operation was performed.

Dr. H. Knapp, of New York, reported

A SERIES OF ONE THOUSAND SUCCESSIVE CASES OF EXTRACTION OF CATARACT WITH IRIDECTOMY.

These 1,000 cases were operated on during the years from 1866 to 1886. A tabular statement was given showing the results obtained in each series. V = $\frac{20}{cc}$ to $\frac{20}{xx}$ was considered a good result; V = $\frac{21}{cc}$ to $\frac{1}{cc}$ was considered a moderate result; and where V = less than $\frac{1}{cc}$ the case was considered a failure.

In the first series of cases the method of extraction was by a very peripheric section, more curved than linear, with the following results—good, 70 per cent.; moderate, 22 per cent.; failures, 8 per cent. Of the failures, 3 per cent. were from suppuration. In the second series a peripheric linear section was employed. Results—good, 87 per cent.; moderate, 12 per cent.; failures, 2 per cent., all from suppuration. In the third series linear section was employed. Results—good, 86 per cent.; moderate, 9 per cent.; and failures, 5 per cent., 3 per cent. of which were due to suppuration. The fourth and fifth series were performed by peripheric linear section, with removal of the anterior capsule. Results—good, 82 per cent.; moderate, 7.5 per cent.; and failures, 11.5 per cent., of which 8.5 per cent. were due to suppuration. In the sixth series, in which peripheric linear incision with peripheric capsulotomy was performed, the results were—good, 89 per cent.; moderate, 1 per cent.; and failures, 10 per cent., of which 8 per cent. were due to suppuration. The seventh series was operated on by the same method, only the section was less peripheral. Results—good, 88 per cent.; moderate, 7 per cent.; and failures, 5 per cent., of which 2 per cent. were due to suppuration. The eighth series was operated on by circular marginal section with peripheric capsulotomy, and with antiseptic precautions. Results—good, 90 per cent.; moderate, 8 per cent.; and failures, 2 per cent., of which 1 per cent. was due to suppuration. The ninth and tenth series of cases were operated on in the same way, with the following results—good, 90.5 per cent.; moderate, 5 per cent.; failures, 4 per cent., of which 3 per cent. were due to suppuration. The results obtained, taking the 1,000 cases as a whole, were—good, 85.2 per cent.; moderate, 9 per cent.; failures, 5.93 per cent., of which 3.8 per cent. were due to suppuration.

DR. J. A. SPALDING, of Portland, read a paper entitled

DOES SUNSTROKE AFFECT THE SIGHT PERMANENTLY?

So many pension claimants were now coming forward, asserting that they suffered from sunstroke and permanent loss of sight in the army, and finally became more or less blind, that it is quite desirable for the expert in examining such cases to be supported by greater authority than he is likely to discover in any text-books or accessible literature. In point of fact there has never been reported in the vast extent of ophthalmic literature but a single undeniable case in which sunstroke has been followed by permanent blindness, and only six others in which the eyes were ophthalmoscopically examined soon after the attack. In all of these optic neuritis was distinctly marked, and in several vision was reduced to a low degree, yet ultimately all six recovered perfect vision without much, if any, treatment. The frequent allegations of patients "losing their sight during a sunstroke," or of "a dimness coming over their eyes," are simply descriptive of the incipient stage of unconsciousness, and are untruthful in a scientific point of view. These recollections become in later years the basis of pension claimants' assertions that their vision was seriously affected by sunstroke.

Dr. Spalding expressed the opinion that these were false, and hoped that the members would support expert examiners against the insults of politicians and claimants' friends in refusing to grant pensions for asserted blindness fifteen or twenty years after a sunstroke.

Dr. D. B. St. John Roosa, of New York, gave an account of

A CASE OF PROBABLE QUININE AMAUROSIS.

The patient was a young lady who had been living in a malarious district. While in Washington she had an attack of intermittent fever. Some time after this she was seized with convulsions and unconsciousness. It was believed to be a case of malarial coma, and thirty grains of sulphate of quinine were administered by the rectum on four occasions. On the third day consciousness was restored, but she was then unable to distinguish light from darkness. The pupils were dilated. She had been taking quinine and iodide of potassium before I saw her, which was on October 18, 1886; vision was slightly recovered, and she could count fingers at four feet. On ophthalmoscopic examination the optic papillæ were found small, the vessels very small, but no exudation was seen. Quinine three times a day, with a hypodermic injection of strychnia, was given. The dose of strychnia was gradually increased to one twenty-fourth of a grain, and kept at that for some time. Vision gradually improved. It was at first excentric, but by December 10th she had centric vision of $\frac{20}{lxx}$. The papillæ were still white and the vessels small. The treatment was continued. She returned to her home, and now states that she can see almost as well as she ever could. The urine was tested in this case several times, with negative results.

Dr. Emil Gruening, of New York: I recently saw a lady, fifty years of age, who had been given thirty grains of quinine in one dose. When she awoke in the morning she was blind and deaf. She was deaf for about twelve hours, and absolutely blind for twenty-four hours. I saw her about five days after the attack. The fundus was apparently perfectly normal in both eyes, but the field was much contracted in all directions. It does not seem to me that the ischæmia which has been described in the more severe cases should necessarily be present in the lighter cases of quinine amaurosis.

Dr. Swan M. Burnett, of Washington, read a paper entitled

CLINICAL CONTRIBUTIONS TO THE STUDY OF RING SCOTOMA.

The speaker gave the histories in full of two cases of ring scotoma which he had followed for the space of two years. In one case there was a history of syphilis, and in the other not; in both there was choroiditis, with vitreous opacities. In one case there were no gross changes in the choroid; in the other the changes did not correspond with the defect in the visual field. In one case only one eye was affected; in the other the affection was binocular. In one case the trouble began as a typical right hemianopsia, with left semiannular scotoma. The central clear spot, more or less oval in form, 10 x 20. was never, through all the changes, diminished in size. All who have written on the subject (a full bibliography was appended to the paper) have placed the pathological process inside of the eye, though in none have the changes in the choroid manifest under the microscope been sufficient to warrant such a conclusion, and in none have the changes in the form of the visual field been followed so closely or so long as in these cases, eighteen diagrams of the fields at various times being exhibited. The course of the nerve-fibres in the tract, chiasm, and nerve, as demonstrated by Bunge, Lamelsoker, Leber, Vassius, and others, particularly in the somewhat analogous condition of central scotoma, which in nearly every instance coincided in form and size with the central clear space in these cases, seems to justify the assumption that the fibres supplying the intermediate parts of the retina were hindered in their function either from a localized neuritis or by pressure of the adjoining parts.

Dr. Henry D. Noyes, of New York: A young lady, aged seventeen, came to me complaining of pain and dimness of sight in one eye; the ophthalmoscope showed no material lesion, but with the perimeter I discovered a ring scotoma. There were no local lesions, no symptoms of brain-trouble, and no evidences of hysteria. Further examination showed signs of orbital neuritis; I based this view chiefly on the fact that pressure of the globe backward elicited unquestionable pain. The ring scotoma subsequently entirely disappeared, and vision was restored to the normal.

Dr. C. S. Bull, of New York: I reported, not long ago, a case of a man, aged thirty-six, who when two years of age injured the right side of the skull by a fall; vision of right eye was impaired, and a convergent squint followed. He could count fingers at two feet with the right eye. In 1878 he had a compound depressed fracture over the left parieto-occipital region of the skull. Trephining was resorted to; this was followed by convulsions, which have since grown less marked. He noticed that he could not see through a part of the field of the left eye. The ophthalmoscope shows a neuro-retinitis of low grade in that eye. The field was normal for twenty degrees around the point of fixation, then there was an irregular defect in the field for fifteen to twenty-five degrees; all around and outside of this the field was normal.

Dr. C. S. Bull, of New York, read a paper (see p. 151) entitled

PASSIVE MOTION IN THE TREATMENT OF PARALYSIS OF THE OCULAR MUSCLES.

Dr. O. F. Wadsworth, of Boston, read a paper entitled

RECURRENT PARALYSIS OF THE MOTOR OCULI.

The patient, after an attack of scarlet fever in 1874, when three years of age, had headache recurring every month or so. On February 24, 1879, she was brought to the hospital, with the history that she had suffered with daily pain in the head for two weeks; this was referred to the supra-orbital region. It would commence about noon, then intermit, recur again about five o'clock, and continue for several hours. There was vomiting on the first two days of the attack, and there was a slight discharge from the right ear. She was seen one month later; the headaches had recurred every two or three days; there was then paralysis of all the branches of the right motor oculi nerve, with ptosis and divergence of the right eye. By February, 1887, the headaches had diminished in frequency and for the last few years she has had three or four attacks a year, the more severe being accompanied by ptosis and dilatation of the pupil. It was subsequently learned that with each severe attack there was a free discharge of ill-smelling fluid from the right ear. On May 1st the right ear was examined and a polypus, filling the meatus, found and removed. The writer had been able to find only fifteen cases of this affection on record; of this number, four were males and eleven females. The period between the attacks was variable and irregular. In several instances there was evidently a persistence of a certain amount of paralysis between the attacks; this was noted in the case just described. There has been no instance of permanent relief, and three of the cases have terminated fatally.

As to the cause of the affection, the results of the autopsies point to a basal origin. In one case plastic exudation surrounded the right oculo-motor nerve, in another case the right oculo-motor nerve was pressed upon at its point of emergence from the crus cerebri, and in the third case there was a fibro-chondroma which had developed in such a way as to separate the fibres of the right oculo-motor nerve without destroying them. In the case reported the speaker thought that there was an evident association of the paralysis with the chronic aural trouble.

Dr. J. A. Lippincott, of Pittsburg, read a paper on

HYPERÆMIA IN MUSCULAR INSUFFICIENCY.

The speaker reported several cases of localized hyperæmia of the eye, which he said were due to weakness of

the muscles. The grounds on which he based this view were the form and location of the spot of hyperæmia, and its disappearance, along with other evidences of the muscular insufficiency.

The Society then adjourned until eight o'clock in the evening.

EVENING SESSION.

DR. W. F. NORRIS, of Philadelphia, gave an account of

CASES OF ACUTE PRIMARY GLAUCOMA, OF HEMORRHAGIC GLAUCOMA, AND OF SECONDARY GLAUCOMA.

The first case reported was that of a married woman, aged fifty-two, who was admitted to the Wills Eye Hospital, with acute glaucoma of the left eye. The attack was of twelve days' duration. Vision was much impaired. The right eye was entirely quiet and presented a narrow iridectomy upward. In August, 1875, a severe attack of glaucoma had suddenly occurred in the right eye, and on the fifth day iridectomy had been performed; since then the eye had given no trouble. When admitted to the hospital the patient was in a feeble condition. She was put to bed, a leech applied, and eserine instilled. The eye improved and became quieter; the cloudiness of the cornea and the other symptoms remaining, iridectomy was performed twenty-eight days from the commencement of the attack. A year later she had a severe attack of pain, not relieved by eserine, and stereotomy was performed. The eye continued to give trouble from time to time, and it finally became necessary to enucleate it.

Primary hemorrhagic glaucoma.—Miss B——, aged seventy, was seen in February, 1867, with marked hemorrhagic retinitis and incipient cortical cataract. She stated that she had had a sudden loss of vision two years previously; the present attack of loss of vision came on suddenly ten days before, when the patient was stooping. Examination showed numerous hemorrhages into the retina. One month later the right eye was more cloudy, the tension increased, and there was some hemorrhage into the anterior chamber; iridectomy was then performed; the wound did well until the fourth day, when there was a sudden attack of pain; on the ninth day, apparently without exciting cause, this symptom recurred. After this there would be an exacerbation every few days. The eyeball was subsequently enucleated, the patient dying a year or two later with apoplexy.

Secondary glaucoma after successful operation for cataract.—A man, aged sixty-six, had been operated on for cataract in both eyes some time before coming under observation. This had been done in England, both operations having been successful. Some eighteen months later the right eye had been operated on by a needle-operation, and since then it had not been free from irritation. When seen, the right had lost the perception of light, and the left eye presented signs of sympathetic irritation. The right eye was enuncleated, and this relieved the irritation in the left eye. The patient now sees fairly well.

A number of micro-photographs, showing sections of the eyes removed in these cases, were exhibited by means of a lantern.

DR. B. ALEXANDER RANDALL presented the notes of a case of

SARCOMA OF THE EYELID SIMULATING A MEIBOMIAN CYST,

occurring in a man, aged forty-one, who came under observation in 1885, with the history of two operations in the previous three years for the removal of a cyst. The tumor had the position, size, color, and apparent fluctuation of a chalozion, but a vague grayness suggested pigmentation, and led to its total removal by a V-shaped incision through all the tissues of the lid. Section proved the tumor to be a solid, incapsuled sarcoma of large spindle-cells. The patient passed out of sight for two years, and then returned with recurrence very like the original, which had been treated, in the interim, as chalozion. The outer half of the lid had now to be removed, and the tumor was found to be of the same nature as before and again incapsuled. The meibomian glands at both operations seemed to be entirely normal, and the tarsus was entirely uninvolved.

Dr. Randall also presented some of the ophthalmoscopic cases of cilio-retinal vessels, with the remark that they were far from rare, and that the occurrence of such an origin of even a principal artery or vein, supplying different quadrants of the retina, had come to notice. As to the origin of these vessels, in two cases they could be distinctly seen to join the net-work of the choroid. The reported cases examined anatomically have been seen to arise directly from a short ciliary vessel. Photo-micrographs of such a case, in the collection of Dr. William F. Norris, were shown.

Dr. Randall also called attention to the Hohlschnitt of v. Jaeger in cataract-extraction, as differing in no essential from the modified linear operation, except in the knife with which it is made. He asked attention to the knife, with the claim that, with it, almost all the usual modifications of the linear extraction could be made, but that no aqueous need be lost until the completion of the incision, and, consequently, that the cut could be made more safely and smoothly than was possible with the Graefe knife. As illustrative of the perfection of the healing, he demonstrated a photo-micrograph of a Hohlschnitt executed by v. Jaeger himself, which he had prepared in Professor Alt's laboratory about a year after the operation.

Adjourned.

THURSDAY—SECOND DAY—MORNING SESSION.

DR. H. P. NOYES, of New York, presented a

CASE OF GLIOMA OF THE RETINA.

The patient, a child, was first seen when fifteen months old. The eye was enucleated, and microscopical examination confirmed the diagnosis of glioma, which was made prior to operation. The patient was again seen fourteen and a half years later, when sixteen years of age. An artificial eye had been worn. There was not the slightest evidence of a return of the disease.

Pseudo-glioma.—This case was reported on account of the interest connected with the diagnosis. It was difficult to say positively whether or not there was an intraocular tumor. The case was examined by Dr. H. Knapp and the author, and a diagnosis of inflammatory trouble was made. Enucleation was advised on account of the doubt as to the correctness of the diagnosis, and, even if the affection were purely inflammatory, enucleation was the wisest plan in view of future possibilities. The patient was a boy, aged five, who in November, 1886, had fallen from his velocipede, the handle of the machine causing a wound of the left cheek under the orbit. There was no apparent injury to the eye, and during the following winter there was no trouble. On May 4, 1887, he was first seen by the author. There was at this time a cicatrix one inch below the border of the left orbit. No irregularity of the orbital edge could be detected, and pressure on the globe caused no pain. The movements of the eye were normal, and the pupil active. The iris had a slightly greenish hue. An extremely vascular growth was seen with ease. This appeared to fill the fundus. After consultation it was deemed advisable to enucleate the eye. This was done, the wound healing promptly. Examination showed that there had been cyclitis, with inflammation of the vitreous, with the production of a mass of inflammatory tissue extending across the eye behind the lens, forming a perfect septum. The retina was totally detached, and the choroid was partially detached. There was also marked hypertrophy of the tis-

sues at the base of the orbit. It was thought that the original process had been an injury to the floor of the orbit.

Dr. Noyes also reported a case of prolapse of the lachrymal gland: C. S——, aged twenty, who consulted him on account of a swelling in the upper lid of the right eye. This had been growing for nine years; it could be freely moved over the globe, and moved with movements of the eyeball. There was no history of injury or of inflammation of the eye. The mass was removed, and found to be a displaced lachrymal gland. The removal has been followed by no unpleasant effects. Four cases of displacement of the lachrymal gland are on record.

While in theory the operation for the relief of entropion of the lower eyelid is very simple, yet in practice it often fails to accomplish the desired end. The author described an expedient which he had employed four years ago. He excised a piece of skin below the border of the lid, and then dissected up a flap, leaving an open wound. He next freshened a spot on the outer border of the lower lid, taking out a piece of conjunctiva. He then turned the flap upward, and attached it to the freshened surface. This little flap served to hold the lid in a position of eversion. In one week the stitches were removed. The patient then disappeared, and was not seen for four years. It was then found that the lid remained in a natural position. The little bridge of skin still was present, and under it there was a sinus through which a probe could be passed. The piece of skin was divided, and the result was perfect.

Dr. Samuel Theobald, of Baltimore: In connection with the case of glioma, I would mention one that has gone nine and one-half years without a return. The only weak point in the case is that no microscopical examination was made. The macroscopical appearances were, however, characteristic. The operation was done when the boy was six years of age. The boy is still perfectly well, and there is no suggestion of the return of the disease.

Dr. H. Knapp, of New York: Until lately I have held the view that there was such a thing as the permanent cure of glioma, but now I am very doubtful if this is ever accomplished. There are exceptional cases which do not terminate fatally until ten or fourteen years after operation. They then die from a return of the local disease, or else from a generalization of the condition. Graefe said that all of these cases died.

Dr. Emil Greuning, of New York: I have seen two cases in which there has been an apparent immunity from the return of glioma. The first case was operated on in 1875; the patient was a girl five years of age. The optic nerve was not involved. The girl is still under observation and in perfect health. The second case, a child, aged one year, was operated on in May, 1880. It was a case of true glioma, with no involvement of the optic nerve. The child is still perfectly healthy. Both of these patients have been wearing artificial eyes since the operation.

Dr. W. F. Mittendorf, of New York, called attention to

A PHENOMENAL PULSATION OF THE INTERIOR OF THE EYE.

The patient, aged fifteen, came under observation for asthenopic trouble. He showed no signs of disease. The tension of the eye was normal and the fundus was normal. There was no pulsation of the arteries or veins, but pulsation could be induced by pressure. A short distance above the disk there was a grayish-white band stretching from one vein to the other, and looking like a little sac filled with fluid. In the middle this band presented a little point. This band presented distinct pulsation, which corresponded with the cardiac pulsations. The patient was seen a number of times, and the appearance was always the same. A little higher up, and more to the nasal side, there was a similar band connected with an artery. This did not pulsate except when pressure was made. It was thought that the band was composed of connective tissue, which was thrown into vibration by the meeting of the vibration of the two veins with which it was connected.

Dr. Edward Jackson, of Philadelphia: I recently saw in a case that presented no spontaneous pulsation a little band extending from the perivascular sheath, which was thrown into vibration with each radial pulsation. This condition occurred in both eyes.

Dr. Lucien Howe, of Buffalo, read a paper on

INCREASE OF BLINDNESS IN THE UNITED STATES.

The author called attention to the fact that while the population during the ten years from 1870 to 1880 increased at the rate of thirty per cent., blindness during the same time increased over one hundred and forty per cent. By means of a diagram this percentage of increase in each State separately was shown. The statistics also show that blindness increased in an almost constant ratio from north to south in the United States, and that it decreased in the same way from east to west. This was also shown by colored maps. The cost of sustaining this army of over fifty thousand blind was estimated, on the lowest basis of cost, and of wages which would have been earned, at over sixteen million dollars in 1880, or over twenty-five million in 1887. As for the causes, contagion was found to exercise the most important influence. Immigration was also considered as an important factor, in view of the large number of contagious diseases of the eye introduced every year into the country, and the laxity or absence of quarantine regulations regarding them. As for the prevention, suggestions were offered, first, as to the care of new-born children; second, the isolation of suspicious cases in residential schools and other institutions, even for adults also; third, the instruction of the public as to the advisability of guarding against contagious forms of disease.

In connection with this matter Dr. Howe offered the following resolutions:

Whereas, The census reports indicate that there has been an increase in the number of blind in the United States more than four times as great as that of the total population, and

Whereas, An inquiry as to the causes of this shows that it is largely due to contagious diseases of the eye, therefore

Resolved, That a committee of three be appointed to examine further as to this apparent increase, and recommend means for its prevention.

Resolved, That the President of the United States and the Secretary of State be respectfully requested to furnish this committee with whatever letters or other recommendations may be necessary to further their investigations in this country or elsewhere.

Resolved, That the officials in charge of residential schools and similar institutions also be requested to assist the committee to any extent in their power.

These resolutions were adopted, and the President announced Dr. Lucien Howe, of Buffalo, as chairman of the committee—the other members to be appointed subsequently.

Dr. Charles A. Oliver, of Philadelphia, read a paper on

THE EYE OF THE ADULT IMBECILE.

The speaker presented the following conclusions:

First.—The eye of the male adult imbecile is an organ which is capable of proper functional activity.

Second.—By reason of early mental incapacity the ordinary appearances seen in the used eyes of the mentally healthy are lessened in due proportion to the amount of work given to the organ.

Third.—The eye of the imbecile, being practically an unused organ for close and careful near work, the distention of the globe and the elongation in its visual axis,

with consequent increase in index of refraction, is almost entirely avoided; this being in direct ratio to use.

Fourth.—The want of these physical changes may be considered as significant of a type of unused healthy, adult, human eyes.

Fifth.—The healthy eye of the imbecile serves to teach us that the various conditions seen in the used eye of the mentally healthy must be considered as pathological changes, the representatives, not only of general want of tone, but of constant and frequent abuse of a delicate organ.

Dr. Charles A. Oliver also exhibited water-color sketches of a case of double chorio-retinitis with partial degeneration of the optic nerve, associated with curious lymph-extravasation into the retina and vitreous, in a boy, twelve years of age, who had had an attack of basilar meningitis five years previously, at which time eyesight became bad. No hereditary dyscrasia could be discovered. Vision was greatly reduced, and patellar tendo-reflex was almost abolished.

Dr. S. D. Risley, of Philadelphia, reported

ADDITIONAL CASES OF HYPERMETROPIC REFRACTION PASSING WHILE UNDER OBSERVATION INTO MYOPIA.

The most important measure in the treatment of these cases was considered to be the use of correcting glasses. When we consider the large number of cases which at the first present the same conditions as the cases reported, and who have subsequently had no return of the trouble, we cannot but think that the group of cases now presented are only those in which the treatment has failed, and that without their correcting glasses a much larger number would have pursued the same history. A study of these cases has demonstrated to the author the importance of astigmatism, when present in very low degree, as a factor in setting up those changes in the nutrition of the eyeball which result in impaired resistance to even normal intra-ocular tension.

Dr. Samuel Theobald, of Baltimore, read a paper entitled

THE PATHOGENESIS OF PTERYGIUM.

The generally accepted theory of Arlt, that pterygium has its origin in a marginal corneal ulcer, to which a tag of conjunctiva has become attached, he thought was untenable, because if this were its usual mode of origin pterygium would be found approaching the cornea from every possible direction, since marginal corneal ulcers are not apparently more frequent in one position than in another. It is known, however, that such is not the case, but that pterygium is almost always situated directly over the recti muscles, and that in a very large proportion of cases it is over the rectus internus. The more recently proposed theory of Poncet, that pterygium is due to the presence of microbia, which tunnel their way under the corneal epithelium, is open to the same objection, for this also assumes the existence of a precedent corneal ulcer. The view long held, that conditions which tend to induce chronic hyperæmia of the conjunctiva favor the formation of pterygium, he thought was well established.

Assuming that this view is correct, are there reasons why a localized hyperæmia of the conjunctiva should be of frequent occurrence where pterygium usually forms to the nasal side of the cornea? This was answered affirmatively. The close connection between the vessels of the recti muscles and those of the anterior portion of the conjunctiva were referred to, and it was pointed out that the determination of blood to these muscles might influence the blood-supply of the overlying conjunctiva, and that this would be the case especially with the recti interni, since they were the largest of the straight muscles and in close relationship with the conjunctiva, because attached to the sclerotic nearer to the corneal border than any of the others. Abnormality in the distribution of the blood-supply of the internal recti muscles, and of the overlying conjunctiva, and, more frequently still, disturbance in the normal relationship between convergence and accommodation, such as insufficiency of the internal recti muscles, the different varieties of ametropia—these were regarded as the usual causes of pterygium through the localized hyperæmia of the conjunctiva to which they give rise.

Dr. Samuel Theobald, of Baltimore, also presented a case of

RECURRENT RETINAL HEMORRHAGES FOLLOWED BY THE OUTGROWTH OF NUMEROUS SMALL BLOOD-VESSELS FROM THE OPTIC DISK.

The case reported was that of a lady, aged fifty-two, in whom menstruation had recently ceased. During a period of nine months she had suffered with recurrent hemorrhages into the retina and the posterior part of the vitreous humor of one eye. The macula escaped serious involvement, and central vision was but little affected. The hemorrhages were supposed to be due to thrombosis of one of the larger retinal veins. Finally a nebulous outgrowth from the optic disk, extending forward into the vitreous humor for some distance, made its appearance. This consisted of numerous small and nearly parallel blood-vessels, running from behind forward, and held together by semi-opaque tissue, the outline of which could be easily distinguished from the surrounding vitreous. When last seen this growth had diminished somewhat in size. The prognosis was regarded as favorable, the development of new vessels being looked upon as an effort of nature to repair the damage caused by the repeated hemorrhages.

Dr. W. H. Carmalt, of New Haven: On February 17, 1877, a gentleman presented himself to me complaining of sudden blindness in the left eye. I found it filled with blood, which prevented a thorough examination. A month later examination showed nothing peculiar, except traces of coagula in the vitreous. On August 3d of the same year he began to complain of affection of the other eye. On this occasion Dr. Noyes examined the eye and found hemorrhages into the vitreous of the right eye. The condition cleared up in that eye, and on June 3, 1878, the eye was again affected. These attacks have continued to recur every few months.

Dr. B. E. Fryer, of Kansas City: I would ask, with reference to the cases of recurrent hemorrhages, whether or not attention has been directed to scurvy as a cause? I have seen one case of recurrent retinal hemorrhage which I thought was due largely to that cause.

Dr. H. Knapp, of New York: I wish to say a word with reference to treatment. The main point is not to fatigue the eyes, and to put them at rest early in the evening. A waitress in a New York family suffered from hemorrhages every time the family gave an evening party. She was sent to the country and the hemorrhage cleared up. She returned and served at an evening party, and again the eye filled with blood. She has now given up service, and for two or three months has had no trouble. The treatment consists in rest, and in avoidance of everything that would produce a dropsical condition of the blood.

Dr. G. C. Harlan, of Philadelphia, read a paper entitled

EMBOLUS OF THE CENTRAL RETINAL ARTERY.

The patient was a clerk, aged fifty-two, in good general health. While reading, in perfect comfort, a shadow suddenly appeared before the left eye, and on closing the other he could just distinguish large objects about the room "through a brownish haze," and in a few minutes sight was entirely gone.

An ophthalmoscopic examination made the next morning showed an extensive œdema of the retina, giving the whole fundus a grayish tinge; disk pale, and its margins blurred; arteries very pale, although not much narrowed, and some of the smaller branches lost in the retinal

œdema; larger veins contracted in places, particularly in and near the disk, but generally of full calibre; phenomenon of visible slow continuous circulation of blood in bead-like sections, well marked in superior temporal artery and vein; macula occupied by bright-red patch, oval in form, with its long diameter horizontal, and several minute terminal vessels in its neighborhood enlarged and apparently isolated; two small dots of retinal hemorrhage at outer margin of disk. The œdema increased decidedly for the first few days, and then gradually subsided. There was still a little remaining on the nineteenth day; after which the patient was not seen for three weeks, when the color of the fundus was normal. The visible circulation lasted only about a day and a half, disappearing first in the artery. The veins refilled at their narrowed portions, and retained nearly their full calibre; while the arteries became paler and narrower until only the two main trunks could be seen, and these showed white lines along their margins from perivasculitis. The spot at the macula gradually disappeared. The disk regained the distinctness of its outlines, but remained dead-white. Colored plates were shown illustrating the first and the final appearance of the fundus.

The pathology of the case was evry obscure. The heart and kidneys were normal, and there was no symptom of degeneration of the arteries. A caries of the middle turbinated bone on the same side, from long-standing nasal catarrh, was not thought more likely to act as a cause than would be a similar local disease in any other part of the body. The only possible causes seemed to be that some product of the nasal disease might have found its way into the general circulation and lodged in the retinal artery; that an embolus might have been formed of a fragment washed from a parietal thrombus in some distant vessel; or that the obstruction might have resulted from disease in the retinal artery itself.

Dr. David Coggin, of Salem, Mass., read a paper entitled

CHRONIC GLAUCOMA,

describing a case, the object being to elicit discussion as to the best method of treatment.

Dr. George C. Harlan, of Philadelphia, read a paper on

DANGER TO IRON-WORKERS FROM THE USE OF OLD HAMMERS.

A hammer was shown from which a fragment had split off, injuring the eye of a workman. The constant concussion of the hammer causes it to assume a crystalline condition and become very brittle.

Dr. Myles Standish, of Boston, gave an account of

A CASE OF RETINITIS PIGMENTOSA TREATED ELECTRICALLY.

The patient was a woman, aged thirty-three, and was myopic 1.50 D.; she had worn glasses since she was seventeen years of age. When first seen, on April 14, 1886, her sight had been failing for three years, and for the last three months had failed very rapidly, so that she could not go on the street alone after dark. Upon ophthalmoscopic examination characteristic patches of retinitis pigmentosa were found in the periphery of the fundus of each eye.

Her vision was—right eye, $\frac{12}{40}$; left eye, $\frac{12}{50}$; and the fields of vision were limited to less than 20° in the vertical and horizontal axes.

The only treatment has been the use of the constant current, of such strength as could be easily borne. This has been applied once in five days during the last fifteen months. Her present vision is—right, $\frac{12}{XXX}$; left eye, $\frac{12}{XV}$; and the fields of vision have now vertical and horizontal axes of 70°. She now goes on the streets after dark with safety.

Dr. C. H. Williams read a paper on

ASEPTIC CATARACT-EXTRACTION, WITH IRRIGATION.

The author reported five cases of irrigation of the anterior chamber, after extraction, with a one-half per cent. solution of chloride of sodium, as recommended by Dr. McKeown. Instead of a syringe a glass flask was used, bearing two glass tubes blown in the side. One of these was drawn out to a fine nozzle that could be easily inserted into the anterior chamber; the other had a rubber tube and mouth-piece attached, so that the pressure of the stream could be controlled by the operator. The flask had a capacity of 50 c.c., more than enough to complete any irrigation without removing the tube from the eye. The irrigating instruments and the two-per-cent. solution of cocaine were sterilized in the steam sterilizer, and this was not found to injure the anæsthetic properties of the cocaine. The rest of the instruments and the dressings were sterilized by dry heat at a temperature of 150° Cent. In order to determine the efficiency of the solution of the biniodide of mercury used for the preliminary washing out of the conjunctival sac, some experiments with plate-cultures were made at the laboratory of the Harvard Medical School, through the kindness of Dr. Ernst. An equal amount of the biniodide of mercury and the iodide of potassium were dissolved in water, and added to ten per cent. nutrient gelatine, to give a series of strengths up to 1 to 5,000 of the biniodide to the gelatine. Ten days after exposure to the air of the laboratory for six and one-half hours no growth of bacteria were found on any of the plates, although on the unprotected plates exposed at the same time there was an abundant development of colonies of bacteria. Gelatine of the strength of Pana's solution (1 to 20,000) was then tried, and these plates, after four days, showed an average of 1.5 and 0.8 colonies of bacteria to the square centimetre of surface in the two series of plates, while on the unprotected plates the average was 10.5. In two of the cases of extraction a suture was passed through the piece of conjunctiva above, and this held the wound well in apposition. All of the extractions were done without iridectomy, and a layer of iodoform was dusted on the edge of the closed lids just before applying the bandage.

Dr. O. F. Wadsworth, of Boston, read a paper on

A CASE OF CONGENITAL ZONULAR GRAYISH WHITE OPACITY AROUND THE FOVEA.

The patient was a child eleven months of age. She was unable to sit or stand, and could not hold anything in her hands. She appeared to take little notice of anything. Externally the eyes were normal. With the ophthalmoscope the disks did not seem to vary from the normal appearance. The macula was dark red, and surrounded by a grayish-white opacity. The remainder of the fundus appeared to be normal. There appeared to be some light-perception. Five months later there seemed to be no perception of light. The disk was sharply defined; the central vessel small. The mother had had four healthy children. The fifth, according to the history, had been sick in a similar way as the one under consideration. In all the reported cases some weakness of the general muscles was noted.

Dr. O. F. Wadsworth, of Boston, read a paper entitled

SEPARATION OF THE RETINA IN BOTH EYES, WITH ALBUMINURIA OF PREGNANCY—REPLACEMENT.

The patient was a married woman, seven and one-half months pregnant; about the beginning of the eighth month œdema of the eyelid appeared. This was soon followed by indistinctness of vision. The urine was loaded with albumen, and contained hyaline and granular casts. When seen by the speaker there was a general separation of the retina in the right eye. In the left there was also separation of the retina, but not so

distinct. After consultation it was decided to induce premature labor. This was done, and a living child was delivered. Before the completion of labor a convulsion occurred, for which bleeding was resorted to. The patient convalesced, and vision gradually returned. When last seen the disks were clearer. No separation could be made out in either eye.

Dr. B. Alexander Randall, of Philadelphia, read a paper describing

A CASE OF COLOBOMA OF THE OPTIC NERVE.

Dr. F. Buller, of Montreal, Canada, read a paper describing

A PECULIAR FORM OF GRANULAR CONJUNCTIVITIS ASSOCIATED WITH ICHTHYOSIS.

Two cases in which this combination was present were reported.

Adjourned.

Afternoon Session.

Dr. W. S. Dennett, of New York, exhibited an ophthalmoscope in which the mirror was substituted by an electric light.

Dr. Lucien Howe, of Buffalo, presented a small pocket-ophthalmoscope with movable disk.

Dr. Howe also exhibited several photographs of the interior of the human eye.

Dr. Edward Jackson, of Philadelphia, presented

A SET OF SMALL TEST-LENSES WITH A MODIFIED TRIAL-FRAME.

Dr. S. D. Risley, of Philadelphia, described an

OPHTHALMOSCOPE WITH CYLINDRICAL LENS.

The ophthalmoscope is of the usual form, but behind the mirror there are two slides containing the cylindrical glasses. In one slide the cylinders are +.50, 1.00, 1.50, 2.00, 2.50; in the other, +.25, .30, 4.00, 5.00, and 6.00. With these numbers any desired combination can be made. The axes of the cylinders are rotated by rotating the instrument as a whole. The instrument is especially useful at the bedside for the purpose of correcting a high degree of astigmatism when present.

Dr. Swan M. Burnett, of Washington, D. C., presented

A MODIFICATION OF THE REFRACTION-OPHTHALMOSCOPE, WITH AN ATTACHMENT FOR USING CYLINDRICAL LENSES.

The modifications of the ophthalmoscope which were offered by the speaker consisted, first, in a clip behind the instrument into which the cylinders in the test-case can be inserted. The inclination of the axis is read on a graduation on the back of the mirror. The author had found this arrangement satisfactory in verifying the diagnosis of astigmatism made by other methods, and for examining the fundus of the astigmatic eye free from its anomalous refraction. Secondly, two superposed disks containing lenses, which singly and by combination give 47 numbers (22 plus and 25 minus lenses), with a regular interval of 0.5 D. up to 10.5 plus and minus. Thirdly, a plane circular mirror, with a concave tilting mirror swung in front of it. The plane mirror does not interfere with the tilting mirror when in use, and when it is desired to use the plane mirror alone the tilting mirror can be detached from its upper bearing and swung downward, out of the way, on its lower bearing. The instrument is very light. It is made by Queen & Co., of Philadelphia, and its cost is about twenty dollars.

Dr. John Green, of St. Louis, gave an account of

TRANSIENT MYOPIA FOLLOWING IRITIS.

In 1867 the speaker had been the subject of iritis involving both eyes. During convalescence he noticed that the dimness of vision was not wholly due to lack of transparency of the media, and that vision was improved by the use of concave glasses. He had occasionally observed in other patients with iritis that as they recovered vision was benefited by the use of concave glasses. Last April the speaker had iritis affecting the left eye. He was then able to compare the one eye with the other, and found that the myopia induced by the iritis amounted to 1.50 D. This gradually diminished until it disappeared at the end of four weeks, leaving the normal refraction. He had been unable to find accounts of myopia as a transient symptom during convalescence from iritis.

Dr. O. F. Wadsworth, of Boston: I can confirm Dr. Green's observation with reference to the occurrence of myopia during the convalescence from iritis. Patients who have had no myopia before are benefited by concave glasses. This has gradually grown weaker. I have seen this repeatedly, but it does not occur in every case.

Dr. G. C. Harlan, of Philadelphia, reported an interesting case recently under his care.

A young man, myopic 2½ D., came under observation several months ago, with the history that he had spots coming before the right eye, and that there had been a sudden decrease of vision. I found a certain amount of choroidal irritation and a posterior polar opacity. This began as a six-armed cross with rectangular arms. These became more diffused during the following six weeks. During this time there had occurred a marked opacity in the anterior portion of the lens, without traumatism, and with only a moderate degree of choroid inflammation. There was no special increase in the myopia so far as the author was able to determine.

EXECUTIVE SESSION.

The report of the Committee on Congress of American Physicians and Surgeons was received, and the following resolution adopted:

Resolved, That the American Ophthalmological Society appoint a representative and alternate to the proposed executive committee of arrangements for the congress of special societies, with the proviso that in making the appointment this Society does not commit itself to an approval of the present sketch in all its details.

Dr. William F. Norris, of Philadelphia, was elected representative to the executive committee of the congress, and Dr. D. B. St. John Roosa, of New York, was elected alternate.

The Nominating Committee reported as follows:

OFFICERS FOR ENSUING YEAR.

President.—Dr. William F. Norris, of Philadelphia.

Vice-President.—Dr. Hasket Derby, of Boston.

Secretary and Treasurer.—Dr. O. F. Wadsworth, of Boston.

Corresponding Secretary.—Dr. J. S. Prout, of Brooklyn.

The following were elected to membership: Dr. George Cutter, of Brooklyn; Dr. D. C. Cocks, of New York; Dr. H. S. Oppenheimer, of New York; Dr. Clark McIlvaine, of Trenton; Dr. David Beck, of Cincinnati.

The next meeting of the Association will be held at New London, Conn., on the third Wednesday of July, 1888.

A Conical Rectal Speculum.—Dr. Q. A. Shuford, of Tyler, Tex., describes a speculum devised by himself for use in examining the rectum. It is of the shape of a gradually tapering conical tube, at the smaller end of which is cut a wide slot running more than one-third of the way down the barrel. A plug is inserted into the speculum during its introduction, which closes the slot. After the instrument is in position the plug is removed, and the parts are brought readily into view through the slot. By means of this speculum applications can be made with ease to hemorrhoidal or other tumors in the rectum.

Correspondence.

RULES OF THE NEW YORK STATE BOARD OF EXAMINERS.

To the Editor of The Medical Record.

Sir: A law of 1874 established for the State of New York a State Board of Medical Examiners. Frequent deaths and occasional resignations changed its original membership several times, until, upon the recommendation of the undersigned (who, therefore, objected repeatedly to his own appointment), and for reasons easily understood, all the members of the present Board, with one exception, were selected, by the Honorable the Board of Regents of the University of the State of New York, from among the medical men of Albany, the seat of the Government and the Board of Regents.

The profession never expected the law, as it was passed in 1874, to be efficient. It was believed by many that some of the medical colleges objected to the establishment of a State Board altogether, though others were known to favor it. It was certain that sectarian influences succeeded in undermining the passage of the original bill and emasculating it. *It is certain* that no State Board of Examiners will ever benefit either the profession or the public—both of which stand in equal need of it—before the license to practise medicine will depend on the *compulsory* passing of a successful examination before the State Board. As the law stood, nobody ever applied for examination and the degree of M.D. of the University of the State of New York, who was in the possession of a diploma from a college in good standing. Such few as volunteered to come forward were men who had previously failed in their college examination, or "practised medicine" without study, knowledge, or any title whatsoever. There being no rules and regulations referring to a minimum of accomplishments or requirements, a few of these were let loose upon the unsuspecting public with a diploma; the majority, however, failed.

When the new Board was appointed in the beginning of this year, its members accepted their positions upon the condition that the Board of Regents would authorize a number of rules and principles which were to regulate the examinations. As such have been approved by the Regents, I am directed by the Board of Examiners to present them to you, for your information and, if you deem proper, for publication and comment. We know quite well that, as long as the examination by the State Board is not made *compulsory*, any number of rules and principles will prove their inadequacy and inefficacy again and again. But the present Board hopes that its earnest recognition of the rights and dignity of medical science, art, and practice will be admitted by, and found acceptable to, the profession, and that the latter, after a minimum of requirements for the admission into the ranks of the profession has been officially accepted by the Regents, will feel encouraged to continue its exertions in behalf of both the elevation of the standard of medical education and the protection of the public.

Not one of the recent applicants for a degree has proved successful. One of them had failed in his college examination a few weeks previously, and now threatens to swell the number of graduates of the "university" of a neighboring State. Similiar occurrences are not rare at all. Candidates failing in one college will obtain their degrees from other colleges in the same or other States. Will not that suggest the necessity instead of a "State Board" of a United States Board of Examination?

Very respectfully,

A. Jacobi, M.D.

110 West Thirty-fourth Street,
New York, July 25, 1887.

State Board of Medical Examiners.

The members of the State Board of Medical Examiners accept their positions with this understanding:

A candidate for the degree of Doctor of Medicine, to be given by the Board of Regents, either desires an additional degree after he has received a diploma from a chartered medical college, or he has no diploma from any chartered medical college, and desires or prefers one from the Board of Regents. The degree given by the Board of Regents is to be, or become, an honorable distinction. It must be the object of the law to protect the people and to ennoble the medical profession, and not to facilitate the entrance into it of persons unfit or unqualified. The profession does not require larger numbers, but does insist upon an elevated standard. Therefore, the examination must be strict, and must be conducted according to the following rules:

1. The examinations before this Board shall be conducted in the English language, exclusively.

2. The candidate shall be allowed two and a half hours for each examination. The examination shall be in writing. The candidate must not consult books, extracts, notes, or persons, and must not communicate with anyone during the two and a half hours allotted to him. To do so is to be considered a failure to pass.

3. The examination in clinical medicine and in clinical surgery shall consist in the actual examination of patients by the candidate, and a discussion in regard to the diagnosis, prognosis, and treatment of the cases.

4. The examination in chemistry shall include the actual testing of a specimen of urine, in regard to its reaction, specific gravity, and the presence or absence of albumen and sugar.

5. Each examiner shall have the privilege, if he so desire, of supplementing his written examination by an oral one, in the presence of two other members of the Examining Board.

6. The scale of marks shall be from zero to ten; ten being perfection, and anything below six being a failure to pass the examination.

7. The questions and answers, with their marks, shall remain in the possession of the Board of Regents, and shall be open to inspection.

8. When the candidate shall have completed all his examinations the Board of Examiners shall meet and hear the result of the examination in each branch. And within ten days thereafter, each member of the Board shall make a written report as to the merits and acquirements of the candidate; being guided in this report, not alone by the result of the examination in his particular branch, but also by the result of the examinations in the other branches. And each member of the Board shall send his report, together with the questions and their answers and their marks in his branch, to the secretary of the Board of Examiners; to be by him transmitted to the secretary of the Board of Regents.

And, furthermore, it is the opinion of the Board of Examiners: That in order to receive the degree of Doctor of Medicine, the candidate should successfully pass in every branch; or at least in every branch but one.

State Board of Medical Examiners.

Abraham Jacobi, M.D., President, Examiner in Pathology.

Albert Vanderveer, M.D., Vice-President, Examiner in Surgery and in Clinical Surgery.

Henry Hun, M.D., Secretary, Examiner in Clinical Medicine and in Materia Medica and Therapeutics.

James P. Boyd, M.D., Examiner in Obstetrics.

Franklin Townsend, M.D., Examiner in Physiology.

Samuel R. Morrow, M.D., Examiner in Anatomy.

William Hailes, Jr., M.D., Examiner in Histology.

Willis G. Tucker, M.D., Examiner in Chemistry.

Blind Gynecologists.—The latest Eastern practice which has been introduced is that of having a blind man to make the digital examinations in a gynecologist's office. A Chicago gynecologist is the innovator.—*Medical Age.*

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 24 to July 30, 1887.

MAGRUDER, D. L., Colonel and Surgeon. Granted leave of absence for one month, to take effect on or about August 10, 1887. S. O. 170, A. G. O., July 25, 1887.

CALDWELL, D. G., Major and Surgeon. Order relieving him from duty at Fort D. A. Russell, Wyo., and assigning him to duty at Fort Assiniboine, Mont., is revoked. S. O. 168, A. G. O., July 22, 1887.

CLEARY, P. J. A., Major and Surgeon. Ordered to Fort Assiniboine, Mont., instead of Fort D. A. Russell, Wyo. S. O. 168, A. G. O., July 22, 1887.

MCCLELLAN, ELY, Major and Surgeon. Detailed as member of a board of survey to meet at the Medical Purveying Depot, St. Louis, Mo., on August 1, 1887. S. O. 173, A. G. O., July 28, 1887.

COWDNY, S. G., Captain and Assistant Surgeon. Granted one month's leave, to take effect on or about July 24th. S. O. 79, Department of Texas, July 13, 1887.

BURTON, H. G., Captain and Assistant Surgeon. Sick leave of absence extended three months. S. O. 171, A. G. O., July 26, 1887.

GARDNER, E. F., Captain and Assistant Surgeon. Ordered for duty at Fort Reno, Ind. Ter. S. O. 170, A. G. O., July 25, 1887.

BLACK, C. S., First Lieutenant and Assistant Surgeon. Ordered for duty as Post Surgeon, Fort Bliss, Tex., during the absence, on leave, of Captain S. G. Cowdny, Assistant Surgeon. S. O. 79, Department of Texas, July 13, 1887.

MCCAW, W. D., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Riley, Kan. S. O. 78, Department of the Missouri, July 25, 1887.

THE RECTUM AS A FIELD FOR SPECIALISTS.—The rectum, says the *Medical Age*, is rapidly becoming to the general practitioner what the uterus was to the gynecologist for so many years—an abiding place or point of origin for a great many reflex disturbances. With the proper speculum properly applied, and a blunt hook, the operator reaches into the rectum of his patient. If, on drawing the hook toward him, it catches in a fold or pouch of the rectum, a pus pocket is alleged to be discovered, and is removed with the scissors. The patient after that is alleged to be cured of his reflex disturbances, and progresses on the high road to health and happiness. One man will have his lumbago, another his pain in the top of his head, and yet another be cured of his vertigo and muscular asthenopia by having little snips of mucous membrane cut from his rectum. These little snips of membrane will be found to be the seat of disease; the epithelium softened and infiltrated with white blood-corpuscles; the end organs of nerves in direct communication with the spinal cord and sympathetic ganglia are eroded and irritated by the presence and movements of fæcal masses and gases, until they are pulled down with the blunt hook and excised with the scissors. All the mysterious phenomena said to be induced by physical changes in the uterus and ovaries and bladder may be induced, it is claimed by rectal enthusiasts, by lesions of the rectum and anus.

MARRIAGE OF SCHROEDER'S DAUGHTER.—The approaching marriage of the daughter of Schroeder to Professor Hoffmeier is announced in the German papers.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 30, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	19	8
Scarlet fever	29	3
Cerebro-spinal meningitis	4	3
Measles	35	3
Diphtheria	96	25
Small-pox	2	0
Yellow fever	0	0

TRAINING SCHOOL FOR MALE NURSES.—Dr. F. M. Welles, of Chelsea, Mass., writes that there is a training school for male nurses connected with the McLean Asylum, at Somerville, Mass.

LARGE DOSES OF QUININE.—Apropos of the item in a recent issue of THE RECORD concerning Dr. Knight and his large dose of quinine, Dr. A. T. Bodle, of Grand Rapids, Mich., quotes the following from Burt's "Physiological Materia Medica:" "Dr. Clapton gives a case in which a soldier took an ounce of the sulphate, stirred up in some water, that only produced delirium and stupor. In the famous case of Bazire, five ounces, taken in the course of ten days, caused death."

A SURGICAL CASE AT BUFFALO BILL'S.—"Buck" Taylor, of Buffalo Bill's Wild West Show, now exhibiting in London, has recently become of surgical interest. While performing on horseback not long ago, by a horse running against him he suffered a simple and perfectly transverse fracture of the right thigh bone, at the junction of the upper with the middle third of the shaft. The shortening hardly amounted to half an inch, owing to the direct violence which broke the bone without the aid of muscular force, also partially to the transverse nature of the fracture. The point of special interest surgically was the production of the fracture by direct force, applied to the outer aspect of the thigh. This force was apparently not great in amount, and was without injury to the soft parts. Only a very few such cases have been recorded. "Buck" has become quite a hero, and receives visits from persons of high social position and culture.

THE KARAVAYEFF SCHOLARSHIP IN KIEFF.—A subscription has been raised by the colleagues and admirers of Professor Karavayeff, the eminent Kieff surgeon, for the purpose of founding a scholarship in his honor for students in the medical faculty. It appears, however, that candidates must be of the "orthodox" faith; so that Lutherans, Dissenters, and Jews are debarred the chance of obtaining either the honor or emolument attaching to the possession of a Karavayeff scholarship.

TREATMENT OF BILIOUS HEADACHE.—Dr. Illingworth writes to the *British Medical Journal* that he has obtained the best results with biniodide of mercury in this affection. It is given in pill at bedtime and repeated in from four to six hours if necessary.

THE BERLIN DERMATOLOGICAL SOCIETY was organized toward the latter part of last year, with Drs. Köbner and Lewin as presidents, and Drs. Müller and Rosenthal as secretaries. Meetings of the society are held on the first Tuesday of each month.

BACTERIA AND THE PRICE OF ICE.—"I see that bacteria have been discovered in Hudson River ice," observed Fangle. "Ah!" replied his wife; "that will be another excuse for raising the price, I suppose."

Impotence and Syphilis.—Dr. Bunin relates in the *Russkaya Meditsina* a case of impotence depending upon syphilis, and concludes his paper as follows: 1. Syphilitic affection of the nervous system is expressed sometimes by a single symptom, viz., impotence. 2. The later forms of syphilis may not first declare themselves on the skin. 3. The cause of many otherwise inexplicable cases of impotence may be found in syphilis, and it is important to recognize this fact, not only from a clinical, but also from a medico-legal point of view, since impotence is so often urged as a ground for divorce.

Salol in Sciatica.—Salol is recommended by Dr. Aschenbach, on the strength of personal experience, as a remedy of great efficacy in sciatica. He had been suffering from the affection for three weeks, being confined to the bed, and had tried all the usual remedies without experiencing any amelioration, when he was advised to try the effect of salol. He took seven grains of the drug in the evening and fifteen grains more at midnight. The result was that he slept soundly that night and awoke perfectly free from his trouble in the morning.

The Pathological Significance of Venous Murmurs.—Apetz arrives at the following conclusions from his study of this subject: 1. The venous murmurs perceptible in the internal jugular vein are above all things dependent on the age of the individual affected, and are met with less frequently with increasing age. 2. The venous murmurs audible when the head is drawn to the opposite side are not to be referred to anæmia, but are physiological occurrences. 3. True venous murmurs heard, when the head is held erect, loudly and continuously, in individuals of middle age (twenty to sixty years), have a certain pathological significance; they are not, however, in general to be considered as diagnostic of anæmia. 4. Venous murmurs possess under no circumstances any special diagnostic value in chlorosis or other anæmic conditions.

The Fundamental Cause, or *materies morbi* of chronic disease, Hahnemann, after entertaining the "coffee theory" and the "itch theory," termed *psora—herpetic diathesis* of the French. This malady he considered as at the bottom of seven-eighths of all chronic diseases, the remaining eighth being of venereal origin.—*Homœopathic Recorder.*

Fees of Veterinarians.—Dr J. C. Smith, of Western Texas, writes to the *Medical and Surgical Reporter:* "From personal observation in a number of Western States, I must say that it is a rare exception for a veterinary surgeon to collect $100 per month, and many do not collect half so much for purely professional work, and are *forced* to give some attention to other matters in order to secure a living. Doubtless, in *some* of the Eastern States, veterinary surgeons are better paid; but in the West such men, now, are *pioneers*, and must submit to a pioneer's lot or quit the profession."

Creasote in Phthisis.—Dr. Guttmann, of Berlin, has been conducting a series of experiments with creasote in pulmonary phthisis, and reported his results at a recent meeting of the Verein für innere Medicin. In many cases the administration of the remedy had to be discontinued, because of the nausea and vomiting which it caused. In a small proportion of the cases there was an improvement in the appetite, and in some the cough and expectoration were sensibly diminished; but in general the results do not seem to have been very satisfactory.

A Story about Matthews Duncan.—It is related that a wealthy lady was once sent from the country to consult Dr. Matthews Duncan. On entering his office and being asked what was the matter, she replied: "Oh, doctor, I have so much trouble with my mucous membranes." "Tak' her awa', tak' her awa'," said the gynecologist, in his most decided Scotch, and he refused to have anything to do with a woman who knew that she had mucous membranes.

Mr. W. S. Savory, senior surgeon to St. Bartholomew's Hospital and president of the Royal College of Physicians, was recently offered knighthood by Queen Victoria, but declined the honor, thinking, it is said, that there should have been a baronetcy attached.

A Compliment to American Medicine.—Sir Andrew Clark, in his Cavendish lecture before the West London Medico-Chirurgical Society, on "A Speedy and sometimes Successful Method of Treating Hay Fever," thus spoke of American Medicine: "From America, the most earnest and persevering of all countries at work, we have received the best and largest fruits in efforts to discover the nature and most appropriate treatment of this malady."

A Chinese Anæsthetic.—Dr. Lambuth mentions, in his third annual report of the Soochow Hospital, an experiment made, at the suggestion of a Chinese doctor, with a substance resembling wax, but harder, and semi-transparent (*Medical Press*). This, in the form of a tablet, was cut into small pieces and digested in water for twenty-four hours, together with a small white woody excrescence. The liquid was then found to possess well-marked anæsthetic properties. It was found that a numbness of the lips and tongue was produced, and that the finger immersed in the solution for some minutes could then be pricked with a needle without any pain being felt. The tablet was described as being the juice of the eyes of a frog. It was probably the substance obtained by the Chinese by placing a frog in a jar containing flour and irritating the animal, when it exudes a liquid which forms a paste with the flour. This is then dried and made into cakes bearing some resemblance to button lac.

Ill Effects of a Small Aneurism.—Dr. H. F. A. Goodridge reports in the *Bristol Medico-Chirurgical Journal* for March, 1887, the case of a man suffering from bronchitis, in which there was unusual difficulty in coughing. There seemed to be a hitch or impediment in the act of expectoration, which was very manifest to the patient on attentive observation, and which seemed to be situated high up in the air-passages. Emetics were of little avail, though strychnine afforded transient relief. On post-mortem examination there was found to be a small aneurism of the arch of the aorta, which pressed directly backward on the trachea at a point just above its bifurcation. The author has seen a somewhat similar case, and thinks that it teaches the importance in the mechanism of expectoration of the point where the confluence of the expiratory currents from the two lungs takes place. And he believes that the free and unrestricted play of the trachea at this point is as essential to the efficiency of expectoration as are ciliary action, pulmonary elasticity, and contractile energy of the respiratory muscles, as well as also proper closure of the glottis.

How to Count the Ribs.—Dr. Duroziez states that the best way to number the ribs is not to start from the clavicle, but from the suprasternal notch. If the finger be passed obliquely downward and outward from this point, it will pass to the first intercostal space. Or the sternum may be palpated, and the first prominence encountered in passing from above downward will be the point of union of the first and second pieces of the sternum, opposite which is the second rib.

Expulsion of Foreign Physicians from Russia.—The announcement is made in *Vratsch* and other Russian medical journals that all foreign physicians resident in Russia, but especially those from Austro-Hungary, must become naturalized immediately or get out of the country.

TREATMENT OF FIBROID TUMORS OF THE UTERUS BY ELECTRICITY; WITH STATISTICS.[1]

BY G. APOSTOLI, M.D.,

PROFESSOR OF GYNECOLOGY AND ELECTRO-THERAPEUTICS IN PARIS, FRANCE.

GENTLEMEN: You will permit me to ask of you a temporary suspension of the well-merited celebration of the triumphs of gynecological operative surgery, in which you have held so important a position, while I lay before you my views on a point of conservative treatment.

The surgical measures proposed, discussed, and put in practice for the removal of uterine tumors have of late years occupied a great share of the attention of practitioners, and yet many of the questions connected with this subject still remain undecided, obscure, and perplexing. After all, the dangers of excision are not much less formidable. For this reason I have endeavored to find out a way, neither strictly medical nor strictly surgical, of dealing with these cases by which I might avoid equally the reproach of surgical insecurity and the defect of medical insufficiency. By this I mean my electrical treatment of uterine fibroids. It is now five years since I adopted a proceeding which I may define as a galvano-chemical cauterization of the uterus—vaginal, intra-uterine, or parenchymatous, and always monopolar. For those who have not much exercise in electrical manipulations these few simple words require to be made clear and explained. This I will endeavor to do plainly and shortly.

I may, first of all, point out what my predecessors had done in the electrical cure of fibroids. Apparently they had used a current of electricity, but all the attempts made were defective in ways that I may here recapitulate.

The current of electricity was employed:

First, in a vague and variable manner. Sometimes there was faradization; sometimes there were continuous, sometimes interrupted galvanic currents, but always without a definite object. The current was set in motion in ignorance of its intensity and with imperfect knowledge of the best means of employing it. The proceeding was purely empirical, discrediting a certain agent, capable of doing much good or none at all, according to the skill and intelligence with which it was directed.

Secondly, without dosage; that is to say, without any instrument in the form of a galvanometer, which admitted of measuring the force of the current employed, or of repeating it under the same conditions.

Thirdly, in a dose insignificant, generally so small as to be useless

Fourthly, by a method always extra-uterine, in no way directly acting upon the uterine cavity and but slightly upon the neighboring parts of the vagina.

Fifthly, by a method often dangerous, from the galvano-puncture being made above the pubes and through the abdominal integument.

With these imperfections and dangers in view, it was in 1882 that I originated a new and rational way of using electricity for this purpose. I have since gone on modifying and improving my mode of operating, and I now propose to give you an account of my method as I practise it at the present time.

I have supplanted the old way of operating by a method which is:

1. Precise, by the introduction of new galvanometers of intensity—exact counters and measurers of the electrical current. It is in this way only that we can estimate the value of the fluid passed and utilized through the uterine tissues.

2. Energetic, by an absolutely novel service of high intensities of current which I have progressively carried, according to the necessities of my cases, from fifty to one hundred and fifty and two hundred and fifty milliampères.

3. Tolerable, in spite of the enormity of these doses, in consequence of the introduction of a new form of electrode, the wetted clay, which renders the cutaneous pole innocuous and permits us to transmit through it easily and without injury a current of signal medical intensity.

4. Better localized, by a direct application of the active pole, by way of the vagina, to the uterus, either in its cavity or in the substance of the fibroid deposit.

5. Thoroughly under control, by the exclusive choice of the unipolar method. In fact, I apply to the diseased uterus a continuous galvanic current, of an intensity and duration sufficient to produce the therapeutic effect required. Now, this application, which is generally inaccurately described as electrolytic, ought to be defined as a galvano-chemical cauterization, that is to say, a cauterization purely chemical. In the course of this current through the tissues there are two successive and distinct effects developed.

(*a*) The tangible effect, at the points of entry and exit of the current, which, according to the dose and duration, will be a chemical cauterization more or less severe (but not thermic), variable in conformity with the pole, and different in character at the positive and negative poles. This polar action may, at the will of the operator, be either monopolar or bipolar.

(*b*) The effect resulting from the circulation of the current from one pole to the other, which is, therefore, called interpolar action. This action follows every electrical application and sets up a subsequent process of disintegration, proportionately wide and lasting, of the morbid products through which it is made to pass.

In availing myself to the utmost of the polar and interpolar effects of the electric current for the treatment of fibroma, I adopt always a galvano-caustic, intra-uterine and monopolar. I thus only use directly one active pole, closing the current outside the abdomen by a second pole made as nearly as possible inert. At the same time I reckon upon the interpolar effects of the current, as it necessarily finds its way through the entire uterine substance from the internal pole to the external or cutaneous pole. This, as I have explained elsewhere, is the principal reason why I do not place the two poles in the vagina, and why I advocate the method known as uterine monopolar.

6. More scientifically exact—from the due appreciation of the topical effects of the two poles, and the precise chemical and anatomical indications peculiar to each of them.

I have been able to demonstrate in the clearest manner that we have in our hands a double-edged agent that we can make use of at discretion to afford us local

[1] Read before the British Medical Association, at Dublin, August 2, 1887.

effects quite different. On the one side is a hæmostatic more or less rapid in its action, and either direct and immediate or secondary and remote. I allude to the positive pole, with which we can arrest hemorrhage, either instantly, if the cavity of the abscess be of normal dimensions, if the action be relatively intense, and if the hemorrhage be not excessive; or more deliberately and gradually, after several successive operations, by the formation of contractile cicatrices. The various gradations of the narrowing of the uterine canal are the plain evidence of this secondary and prolonged effect of positive cauterizations.

The positive pole will therefore be the "medicament par excellence" in cases of bleeding or hemorrhagic fibroids.

On the other hand, with the negative pole we obtain a state of temporary congestion, without direct hæmostatic effect. The interstitial circulation of the atoms they momentarily stimulated will be hurried on, and a regression of the non-hemorrhagic fibromata is the consequence, either of this state of congestion or of the supplementary artificial and salutary hemorrhages which take place. The negative pole will therefore be found to render invaluable benefit (though it is possible with the positive pole to arrive at the same point by a way more indirect and tedious) in those cases of fibroids accompanied with amenorrhœa and dysmenorrhœa, which are only too often the despair both of patients and doctors without such means at command.

Looking, therefore, at the difficulties and dangers of abdominal surgery, and at the avowed impotency of the greater part of medication in cases of fibromata, I do not hesitate to assert for my method of treating them a precedence on the following grounds:

1. It is easy of application, since it only requires an elementary acquaintance with the principles and practice of electro-therapeutics; it being unconditionally understood, however, that a profound knowledge of gynecological science must be the indispensable prelude to any attempts.

2. It is simple, for it is ordinarily nothing more than a skilful, uterine, therapeutical sounding. This is only what may be expected of every surgeon provided with a good galvanometer of intensity, some sort of battery capable of yielding an adequate current of electricity, an inoffensive cutaneous electrode in wet potter's earth, an inattackable intra-uterine electrode in platinum, and a steel trocar for the galvano-punctures.

3. The current is mathematically dosable, so that every operator can carry on the treatment under the same conditions, and adjust the force of the remedy to the nature of the effects to be obtained.

4. The seat of operation is optional, for the surgeon has the power of limiting and defining the point of entrance of the current, making it either the mucous membrane or the tissue of the organ.

5. It is of easy control, and only uses an amount of force which should cause neither shock nor suffering, and ought never be put to use but in progressive and adjusted doses.

6. It is antiseptic in itself, by virtue of the high cauterization of the active pole.

7. It is for the most part easily supported, anæsthetics being only required for certain cases of galvano-puncture.

8. It does not impose upon the patients any forced seclusion, and mostly admits of their continuing the usual habits of life, and even of doing hard work, in the intervals between the operations.

9. But, over and above all these considerations, there is a dominant point to be advanced, which alone is of weight enough to turn the scale in favor of electrical treatment. The simple chemical cauterization, for which you may find the equivalent in the laboratory of the chemist, or in the actual cautery, is not the only matter we have to take account of. This chemical cauterization, so called, is only the first part of the therapeutical scene which gradually unfolds itself.

The electrical current, the power we wield and the accompaniment of every vital manifestation, in its course through the tissues acts prolongedly and profoundly on every molecule, and causes ulterior changes in the tumor-structure which may well astonish, both by their extent, safety, and certainty.

I regret I cannot do more on this occasion than roughly outline these questions of prime interest, and I turn at once to the clinical and purely practical results of my treatment.

With this powerful agent, the constant galvanic current of high intensity, of which I have pointed out the tractableness, as well as its many advantages in our hands, let us ask what can it do, and what ought we to be able to do with it, for the relief of the uterine fibroid?

Symptomatically, the fibroids may be divided into two great classes—those which are hemorrhagic and those which are not so.

The positive pole is the express remedy for the cases attended with hemorrhage, the negative pole when they are not hemorrhagic. Each of the two poles conveying the current acts in the first instance locally on that part of the mucous membrane with which it is in contact, the negative pole as producing congestion, the positive pole as hæmostatic. If both, however, in their secondary interstitial action induce a regression of the tumor, I believe in this respect the greater potency belongs to the negative pole. But, beyond this, the negative pole has a further faculty. If we make it enter by puncture into the substance of the fibroid deposit, it will more rapidly insure the diminution of the tumor; and what is truly remarkable is, that this negative pole, naturally causing congestion and little if at all hæmostatic, becomes by a sort of *contre-coup* markedly hæmostatic, and will at the end of a certain time arrest even troublesome hemorrhage.

The stanching effect is due to the cutting off of the supplementary circulation by the rapid atrophy brought about by the action of the negative current.

As a supplement to the rule which I have just formulated—pole positive intra-uterine for the restraining of hemorrhage, pole negative intra-uterine for tumors without hemorrhage—comes the second indication for galvano-punctures. These punctures, as my experience increases, assume daily a more and more preponderating importance in my estimation.

The indications for galvano-puncture are twofold: first, as a matter of necessity in consequence of uterine atresia, or where there is such displacement of the organ as to prevent any introduction of the sound; second, by preference when we see that we cannot advantageously combine punctures with intra-uterine cauterization, so as to expedite and make sure of the effects that with the cauterization we should imperfectly and tardily realize. We must, therefore, undertake the galvano-punctures, alone whenever the case will fairly admit of them, or use them in other cases as adjuncts to the extra-uterine cauterization previously tried.

The manipulations in the operation of galvano-puncture will always be more difficult and even dangerous in incautious hands. I cannot, therefore, too much insist upon a rigid observance of the directions and precautions I have elsewhere given at length. I can now only offer a very short summary of them.

1. Absolute and regular antiseptic irrigation of the vagina, before and after each operation.

2. Use as the puncturing instrument a small steel trocar or needle, and let the puncture be shallow, that is, not deeper than one to two centimetres.

3. Make the punctures on the most prominent part of the fibroid, whenever possible in the posterior cul-de-sac.

4. Make the puncture without the speculum. Slide the trocar through the celluloid sheath which protects the vagina, after having examined and chosen by touch the point where the puncture is to be made.

5. Take the precaution of ascertaining the seat of any pulsation, so as to avoid wounding an important vessel.

6. In case of any unusual hemorrhage, immediately dilate the vagina with an expanding speculum, and if necessary put on pressure-forceps to the bleeding point.

Such is a rapid sketch of the directions for operation. What, now, are the anatomical and clinical results to be expected? They are:

A. As regards the material changes we may affirm that every fibroid tumor submitted to this treatment, sometimes after so short a time as one month, but certainly when the treatment is fully carried out, will undergo a manifest reduction of size, a reduction appreciable by the touch and demonstrable by internal measurement. The further diminution of the tumor, which continues for some months, varying in amount from one-fifth to one-half of the original volume, is generally associated with a coincident and equal accumulation of subcutaneous adipose tissue on the abdominal walls. The regression of the tumor is not only apparent during the time of active treatment, but goes continuously on after it has been superseded, and is the persistent proof of the enduring influence of the electrical operations.

The liberation of the tumor from its local attachments takes place simultaneously with its decrease of bulk. The tumor which at the commencement of the treatment was immovable can progressively be made more and more to change its position as the absorption of the enveloping tissues deposited round it advances.

Another phenomenon is observed in connection with the regression of the tumor. It not only contracts on itself, but shows a tendency to separate from the uterus, to become more distinctly subperitoneal, to detach its mass, as it were, from its setting in the uterine wall, and to remodel itself into a pedunculated form.

B. Clinically the results are not less striking. Perhaps they are even more so, as they are not only matter of proof by the examination of the surgeon, but the patient herself is the living exhibition of them. We may generalize the extent and importance of these results by saying that ninety-five times out of one hundred they comprise the suppression of all the miseries constituting the fibroidal symptomatology. These may be categorically enumerated thus: Hemorrhages, the troubles of menstruation, dysmenorrhœa, amenorrhœa, nervous disturbances, the direct pains in the growth itself and from mechanical pressure and the harassing series of reflex actions.

In a word, the assertion may be safely advanced that, though our therapeutic resources only carry us so far as the sensible reduction of fibroid tumors, and not to their total absorption, we may with regard to the symptoms certainly anticipate their complete removal and the establishment of a state of health equivalent to a true resurrection. I am justified in saying that the greater number of women who have persisted in the necessary treatment not only were cured, but remain well.

I use the expression "greater number" because there is no such thing as human infallibility, especially in medicine. I acknowledge having been sometimes unsuccessful, and so instructive are my failures that I shall recount them at length in a work now preparing. It will be seen that they were cases in which there was no possibility of satisfactory treatment, owing to an apparently absolute intolerance of high intensities of current. I see now that I was wrong in retreating before this supposed intolerance. Among them were three cases of fibroma with ascites, and I now regret that with the aid of anæsthetics I did not persist in going to the limit of my power. I have also met with the same intolerance in some hysterical subjects, in cases of very irritable uterus, and in others of peri-uterine and intestinal phlegmasia. Now, with my present experience, I should not hesitate to operate to the fullest extent under chloroform. There yet remains the obscure question as to the class of cystic fibromata, and tumors with a tendency to malignant degeneration, where there is often a fearful and irrepressible hydrorrhœa accompanying. I have recorded three such instances, and in them intra-uterine galvano-cauterization generally proves useless. Something more is demanded, and we must seek in galvano-punctures a means of denutritive action more powerful and more efficacious.

Finally, I may lay down the following proposition: No operator should admit the failure of intra-uterine galvano-cauterization before having had recourse to the galvano-punctures, which he must use either with or without anæsthetics.

We will now turn aside from all theoretical considerations, and look at the facts. I may rely upon them with confidence, as my great support. I desire, however, in the first instance, to prove the comparative safety of intra-uterine medication when my method is adopted.

Both in my clinic and in private consultations, as far as regards gynecological practice, the application of electricity therapeutically assumes two forms. In the one it is exclusively faradic; in the other, galvanic. For the present I pass over faradism, to occupy myself solely with the patients who have been subject to the treatment by continuous currents.

In the five years from July, 1882, to July, 1887, I have made, either privately or at the clinic, as many as 5,201 applications of continuous galvanic currents, for most of the maladies included in the gynecological nosology, and I may enumerate them in the following order: Fibroids of the uterus, polypi, entire or partial hypertrophy of the uterus, subinvolutions, acute and chronic metritis, ulcerations of the neck of the uterus, peri-uterine inflammations (perimetritis, parametritis, cellulitis, phlegmons), ovarialgia, ovaritis and peri-ovaritis, salpingitis, ovarian and tubercular cysts at an early stage, atresia, hæmatocele.

These 5,201 operations were thus classified:

I.—At my clinic, 2,837.

(*a*) Galvano-cauterizations, chemical, positive, intra-uterine, 1,524.

(*b*) Galvano-cauterizations, chemical, intra-uterine, negative, 749.

(*c*) Galvano-punctures, chemical, negative, vaginal, 368.

(*d*) Galvano-cauterizations, chemical, of neck of uterus, 200.

II.—In my private practice, 2,364.

(*a*) Galvano-cauterizations, chemical, positive, intra-uterine, 1,245.

(*b*) Galvano-cauterizations, chemical, negative, intra-uterine, 1,027.

(*c*) Galvano-punctures, chemical, negative, vaginal, 72.

(*d*) Galvano-cauterizations, chemical, of neck of uterus, 20.

These 5,201 operations, which range over a space of five years, were made upon 403 patients, who went through the treatment more or less systematically. I must not omit to mention that I intentionally say nothing about the number, far in excess of the above, who were made the subjects of faradism, as I intend publishing a separate memoir on that method.

Now, in referring to the history of these 403 patients—276 at the clinic, 127 private—I have only to deplore the loss of two. Of these two deaths I take upon myself the entire responsibility. My method was not at fault. I alone was to blame, as may be seen by the full and detailed report.

In one case, I admit candidly, there was a fatal error in my diagnosis. I did not recognize the presence of a suppurating ovarian cyst, which ended in death from peritonitis. In the second case death was due to a puncture made too deeply. The consequence was intra-peritoneal gangrene, for which the abdomen was not opened.

In addition I have to confess to having either excited or aggravated, in the course of five years, ten peri-uter-

ine phlegmonous inflammations. These must be attributed to blunders in carrying out the treatment, as will be shown when the account is published at length.

But errors of practice happened during the early days of my work, and were either negligence of antiseptic measures, which were either altogether omitted or done imperfectly, or the too violent or too intense use of the negative pole in cases of subacute peri-uterine inflammations.

The fact is, the negative pole, having a strong power of producing congestion, is a dangerous weapon, which at the beginning of any treatment must be used with great prudence and reserve, if one would avoid overshooting the mark for which it is intended.

To lay before you the facts of these accidents will serve the double purpose of warning you of what may befall you and preventing you from making similar errors. My caution is, that whenever the negative pole is put to use, and there is any trace of peri-uterine inflammation present, you must not only redouble your antiseptic heedfulness, but your operative proceedings must be carried on with deliberate carefulness. You must feel your way, testing the susceptibility of your patient by two or three preliminary operations, in which you can give doses so feeble that they only serve to enlighten you and habituate the patient so as to lead on safely to the use of higher intensities.

But when I tell you that this operative gynecology, as I have to practise it, is carried on in such exceptional circumstances that no one else has ventured to encounter them, and upon a class of women who are obliged to walk home shortly after they get up from the couch, who seldom take the necessary rest in bed, and whom poverty forces in some fashion to get through with the ordinary duties of life, you will ask of me with curiosity the explanation of this illusive mystery. All that I can say is, it appears to me that the intra-uterine current, as I use it, seems to have in itself some special antiseptic and atrophic property.

I must close these remarks on the failures, which I have no wish to conceal, but expose to you in all their nakedness, though they stand as the evidence of only the usual difficulties which accompany the laborious and misty development of any new method. I do not speak of other dangers which lie in the way, such as the possibility of concealed pregnancy and accidental abortion, and also the risk of opening up a vesico-vaginal fistula. I have already enlarged on this matter elsewhere, and in my next work on gynecological electrical therapeutics I shall devote a chapter to the needful precautions.

I am anxious to-day, as the completion of my paper, to bring forward a simple statistical statement of what has been my treatment of uterine fibroids.

From July, 1882, to July, 1887, I have had under my care 278 patients with fibromata, or hypertrophy of the uterus, in some manifest degree, upon whom I have used 4,246 applications of currents of electricity. The patients and operations may be thus classified:

I.—Clinic, 186 patients, 2,347 operations.
Galvano-cauterizations, positive, intra-uterine, 1,433.
Galvano-cauterizations, negative, intra-uterine, 593.
Galvano-punctures, negative, vaginal, 321.
II.—Private, 92 patients, 1,899 operations.
Galvano-cauterizations, positive, intra-uterine, 1,085.
Galvano cauterizations, negative, intra-uterine, 746.
Galvano-punctures, negative, vaginal, 68.

As I said before, I do not wish to convey the impression that all these patients have been cured. It is not so, for the reason that some of them have not persevered to the end, especially in the clinic, the attendance having been discontinued upon the first feeling of amendment. But I can affirm that where there has been no negligence, ninety-five times out of a hundred permanent benefit has been acknowledged. I may also predict that, if adopted in its integrity and worked out as it should be, the mortality henceforward will be nothing. The following is a report which gives occasion for melancholy comparison. Among the patients who had not the will to let me finish the work begun, and whose impatience led them voluntarily to seek the removal of their tumors by excision, seven put themselves into the hands of our most eminent surgeons, and not one of the seven recovered from the operation. Comment on this would be superfluous.

One word in parting. Men and their labors can in general only find their proper level and value through the esteem of their associates, and the way in which their work is publicly accepted. If my method ever meets with the confidence of the profession (to speak only of England) it will be mainly due to your illustrious countryman, Sir Spencer Wells, who was one of the first to extend to me the benefit of his experience and authority, and to his learned friend, Dr. Woodman Webb, whose name will ever be coupled with its introduction and diffusion. It would be injustice were I not also to refer to the honor such distinguished gynecologists as the Keiths, father and son, Playfair, Savage, Elder, and others, have done me by their visits, and the encouragement given me by their approbation. I cordially thank all who are present, and assure you that the best recompense of the work of my life will be to find many of you becoming my followers.

EXPERIMENTS WITH STENOCARPINE, THE LOCAL ANÆSTHETIC RECENTLY DISCOVERED BY MR. M. GOODMAN, V.S., AND DR. ALLEN M. SEWARD.

By HERMAN KNAPP, M.D.,

NEW YORK.

As soon as I had read the very remarkable communication of Dr. J. Herbert Claiborne, Jr., in The Medical Record of July 30, 1887, I asked him where I could obtain the above alkaloid. He was kind enough to furnish me fifteen grains of a two per cent. solution. With these I made a number of experiments, which I beg briefly to report.

A. Physiological Experiments.—1. *On the eye.*—The solution, instilled into one of my own eyes, and into the healthy eyes of several other persons, produced *anæsthesia* of the conjunctiva and cornea in the same way and fully as energetically as cocaine of equal strength. In five or six minutes the anæsthesia to the touch was complete, and remained so for ten minutes, then began to diminish, and disappeared in twenty to thirty minutes. An unpleasant *feeling of dryness* set in with the anæsthesia, and lasted the whole day. The *palpebral fissure enlarged*, and the *conjunctiva* was moderately *bleached.* The pallor of the conjunctiva disappeared with or soon after the anæsthesia, but the enlargement of the palpebral fissure lasted for hours.

The *pupil began to dilate* in from eight to twelve minutes, reached its maximum, that of an utmost atropine-dilatation, in twenty minutes, remained in this condition the whole day, was somewhat diminished the next day, still marked on the third day, and disappeared, as a rule, on the fourth. The *accommodation began to diminish* in ten minutes, and was completely paralyzed in twenty or twenty-five minutes. In my left eye a hyperopia of $\frac{1}{24}$ manifested itself, whereas the right, not under the influence of the remedy, showed H $\frac{1}{48}$. Corrected with $+\frac{1}{24}$, my sight was perfectly sharp. The paralysis of accommodation continued the whole of the next day, diminished on the third, and had not yet quite disappeared on the fourth day.

The *tension of the eyeball* during the anæsthesia was very slightly diminished. The interior and mobility of the eye were unchanged. The lustre of the cornea was not conspicuously diminished.

2. *On the nose.*—Four drops instilled into the nose and spread over the mucous membrane rendered the latter

insensible in five minutes; also, the *sense of smell* was almost completely suspended, more so than with like doses of cocaine. The nasal passages appeared freer and wider. This condition lasted ten minutes, and returned to the normal in the next ten minutes.

3. *On the throat.*—Four drops were put on the left side of the pillars of the palate and the adjacent part of the tongue. A sensation of dryness and contraction manifested itself in two minutes, increased for ten minutes, then slowly disappeared in ten minutes more. From the fifth to the fifteenth minute the pharynx was *completely anæsthetic*, it seemed more so than with cocaine of equal strength. Some powdered sugar placed with a curette at the part of the tongue touching the pillars of the palate was not perceived in any way, whereas on the corresponding part of the other side it tasted sweet at once.

4. *On the urethra, glans penis, and rectum.* — Two drops were injected into the anterior part of the urethra, and three drops let fall on the glans. A few drops were injected into the rectum. The effect was the same as with cocaine, fully as strong. The meatus was pale; the urethra anæsthetic in five or six minutes. The sensitiveness in the rectum was reduced, not abolished; probably on account of the insufficient quantity injected. In half an hour the glans was sensitive to the touch again, and the meatus became pink, but was still anæsthetic. In forty-five minutes the normal condition was restored.

5. *On the skin.* — A lady and myself had each two minims injected under the skin of the forearm. In five minutes the sensibility in the place was reduced, in ten to fifteen minutes abolished over an area of 12 mm. in diameter, then it gradually returned. A man (Dr. Weeks) had four minims injected under the skin of his forearm. Anæsthesia as above, but in five minutes he felt constitutional symptoms—dryness in his tongue and throat, a general lassitude, a fulness, kind of stupor, in his head. These symptoms lasted almost half an hour.

Five experiments to produce *anæsthesia by external application of the remedy to a healthy skin gave uniformly negative results.* I had the ear of an eight-year-old girl carefully washed with soap and dried. Six drops were instilled in the concha and held for half an hour, until they were almost evaporated. No insensibility. A place at my forearm and that of a young man seventeen years of age were washed with soap for about ten minutes. When dried, absorbent cotton impregnated with the liquid was applied, covered with oil-silk, and held in position for half an hour. No anæsthesia. The moist pads were reapplied and held twenty minutes longer. No anæsthesia in either case. In order to ascertain whether the skin of the eyelids could be rendered anæsthetic for smaller operations, I washed my left eye and that of a man with soap, dried them, applied the cotton pads steeped in the liquid to the skin, covered them with oil-silk, and fastened them with a flannel roller. Repeated trials for more than an hour manifested *no anæsthesia whatever.*

B. Toxicological Experiments.—Five minims injected into the orbit behind the eyeball of a large rabbit caused in half a minute the most violent attacks of tetanoid convulsions, in which opisthotonus was a prominent feature.

The attacks were repeated every ten to forty seconds. In the intervals the animal lay quiet, with excessively rapid respiration and pulse, and fibrillary twitching in different parts of the body. Touching its body was followed at times by spasms, at others not. This condition lasted fifteen minutes, and the animal appeared as if it were going to die, but gradually rallied, and recovered completely in about forty-five minutes. The eyes from the beginning were staring, the pupils *ad maximum* dilated, and the palpebral fissure enlarged. The cornea had not lost its sensibility completely.

Ten minims injected into the orbit of another, smaller rabbit caused the same symptoms, but less violently and less long.

Fifteen minims in another rabbit produced the above picture in a marked degree. When the animal rallied, it dragged the hind part of its body; the hind legs seemed weak, somewhat paralyzed; the forelegs were moved inco-ordinately, and after an exertion rested on the floor like the spread wings of a bird. The head was raised for a few seconds, but then dropped inert to the floor. Pulse of heart from 160 to 200; could not be counted with accuracy. Respiration accelerated. Condition of eyes as above. The animal recovered in an hour.

Twenty-five minims injected under the skin of a middle-sized rabbit produced the same picture, but very much more slowly. The first convulsive attack set in four minutes after the injection. It was violent, of the opisthotonus and tetanic kind. The attacks succeeded one another at intervals of one-half to one minute. The abdomen was somewhat swollen; condition of eyes, respiration, and pulse as in the others. This animal also recovered perfectly in about an hour. No complete anæsthesia of the corneæ; pupils, however, *ad maximum* dilated, and, as in the other animals, one eye like the other.

Ten minims were injected into the largest vein of one ear of another rabbit. As soon as the liquid entered the blood slight fibrillary convulsions or tremors were noticed over the front part of the body, and as soon as the injection was ended, which was not over ten seconds, *the animal lay down dead.* No respiration, no movement of any kind was noticed. It was doubtful whether the heart still beat; if it did, it was most weak and for not one minute. It was the quietest and most sudden death I have ever seen from any cause. The pupils were not dilated.

The picture furnished by these experiments bears the greatest resemblance to that of strychnine-poisoning.

C. Therapeutical Experiments.—1. *On the eye.*—Some cataract patients (one under the care of Dr. Born) had a drop instilled for the sake of *examination.* The pupils dilated *ad maximum*, and remained dilated three or four days.

A few *foreign bodies* were removed after one drop had been instilled. In five minutes the corneæ were anæsthetic and the operation painless. The pupils remained dilated and the accommodation weakened for three days and a half.

In one case of *acute syphilitic iritis* I instilled one or two drops every five minutes for three-quarters of an hour without producing perfect anæsthesia. The pupil dilated irregularly and only moderately. Then I instilled two drops of a three per cent. solution of cocaine three times during the next fifteen minutes. The pupil remained unchanged, and the centre of the cornea when touched was still sensitive and caused the lids to close as before. The circumcorneal injection, diminished by the stenocarpine, was not influenced by cocaine.

In a case of *acute very painful iritis*, with a *corneal pustule*, stenocarpine caused only a very moderate dilatation of the pupil, even when used in combination with sulphate of atropine. It produced only temporary relief, the same as cocaine does.

In a case of *phlyctenular keratitis* stenocarpine instilled into the eye gave temporary comfort, dilated the pupil, and diminished the photophobia.

In a case of *trachomatous pannus*, with excessive photophobia and blepharospasm, it relieved these symptoms and dilated the pupil.

2. *On the ear.*—In a case of *otitis media purulenta chronica*, with swelling of the mucous membrane in the upper part, repeated instillations diminished the sensitiveness only moderately.

In a case of the same disease, with a small polyp (treated by Dr. Weeks), stenocarpine instillations rendered the polyp anæsthetic, but not the surrounding tissue.

In a case of large *destruction of the drum* and moderate discharge the instillations of stenocarpine made the tympanic cavity almost completely anæsthetic.

I will add that before the instillations the ears had been carefully cleansed and wiped dry.

In one case the *instillations caused general symptoms.* A very painful *furuncle*, situated at the posterior wall, was treated for twenty-four hours with instillations of a warmed solution of bicarbonate of soda. When it had perforated, four drops of stenocarpine were instilled into the ear-canal. The pain diminished, but in ten minutes the patient, a young lady, felt dizzy, nauseated, weak, and fainting. She was very pale. Without removing the stenocarpine, I let her lie down five minutes. She felt better. I forcibly pressed the furuncle out with a strong probe and cleansed the canal with absorbent cotton on a dentist's holder. These manipulations were not painless, but the tenderness was greatly reduced.

D. Conclusions.—From the preceding and Dr. Claiborne's observations, it follows that Drs. Goodman and Seward have presented us with a new local anæsthetic that is very similar to cocaine, chiefly differing from it by its more powerful and lasting mydriatic property. This difference determines its range of applicability.

1. Everywhere, when dilatation of the pupil is desirable —*i.e.*, in all conditions that have a tendency to *congestion and inflammation of the iris*—stenocarpine, either alone or in combination with atropine, is beneficial, and preferable to cocaine.

2. Though its mydriatic effect be less persistent than that of sulphate of atropine, stenocarpine may be used with more advantage when in iritis there is increase of eyeball-tension, a *tendency to glaucoma*, and *when there is great pain.* Further observations have to show whether or not stenocarpine, as other mydriatics, leads to granulations of the conjunctiva. If it do not, it will be very valuable in cases of chronic iritis.

3. Stenocarpine is *inferior to cocaine* when we want anæsthesia without mydriasis, as is the case in the majority of operations—removal of foreign bodies, paracentesis and incision of the cornea, iridectomy, extraction of cataract—more especially when in this operation the iris is spared—operations on the conjunctiva, the lachrymal apparatus, and the eyelids. For an ophthalmoscopic examination, homatropine will be preferable.

4. If we want to be certain of a *complete paralysis of accommodation*, for which stenocarpine is as reliable as sulphate of atropia, stenocarpine deserves preference because its action lasts only half as long.

5. Applied *externally* to *an unbroken cutis, it produces no anæsthesia.* Observations to the contrary mentioned by Goodman and Claiborne must be owing to peculiar conditions which further experience has to determine.

6. *Small doses* (four drops) *rapidly absorbed* may produce *transient general symptoms*—pallor of the skin, cold perspiration, dizziness, stupor, fainting, nausea, and weakness. The same symptoms are produced by cocaine.

7. Larger doses cause the most *alarming general symptoms*—violent tetanoid convulsions, opisthotonus, dilatation of the pupils, excessive acceleration of pulse and respiration, and prostration.

8. *Introduced into the veins*, stenocarpine is the *strongest poison*, causing death almost instantly by arrest of respiration and pulsation.

9. It is certainly dangerous to inject even small quantities into vascular tissues, such as the orbit, for instance ; it appears even unsafe to inject it under the skin in quantities exceeding ten minims of a two per cent. solution—*i.e.*, about 0.01 ($\frac{1}{6}$ grain). We should also be on our guard if we apply it to an open wound during the progress of an operation.

10. *The symptoms of poisoning*, as has been seen from the above description, are like *those from strychnine.* The affinity of the two substances should be further investigated. The chemical tests for the detection of strychnine applied to stenocarpine have proved negative. The reflex excitability from stenocarpine is less than from strychnine, also its toxic effect is considerably less. I instilled into the eyes of a rabbit four drops, and into one eye of another two drops of a two per cent. solution of nitrate of strychnine. Both animals died from tetanoid convulsions in ten minutes. Ten and fifteen minims of a two per cent. solution of cocaine injected into the orbits of rabbits had no general effect.

The alkaloid stenocarpine was separated by Dr. Seward from the leaves of a tree growing in Louisiana, called the "Tear Blanket Tree." From its likeness to the Acacia stenocarpo *he dubbed* it stenocarpine.

August 7, 1887.

DIOXIDE OF HYDROGEN.

Its Administration in the Form of Ozonized Vapor in the Treatment of Diphtheria and Diseases of Pharynx, Naso-Pharynx, Larynx, Nose, Pulmonary, and Bronchial Affections. A New Apparatus for the Production and Inhalation of Ozonized Vapor.

By J. MOUNT BLEYER, M.D.,

New York.

My object in this article is to call the attention of the profession to an agent of remarkable power, having peculiar interest by virtue of its varied utility, and which has been too long in the obscurity from which it now seems to be emerging, only hoping that its vast, dimly foreshadowed possibilities may soon be fully realized.

The hydrogen dioxide, or hydrogen peroxide, as it is generally called, has long been known as a chemical compound, yet it has had no rank as a therapeutical agent until lately. It was discovered in 1818 by Thénard, a French chemist.

Dioxide of hydrogen, $H_2O_2 + 74$ Aq., is a solution in distilled water of anhydrous dioxide of hydrogen, a perfectly clear, colorless fluid, having a slightly prickling taste ; its specific gravity is 1.010 to 1.011, and it contains 2.88 per cent. of the gas. According to E. Schönne, it is a constant constituent of rain-drops and of hail. It is in less amount in snow, and, indeed, is often absent. The greater the size of the rain-drop the greater the proportion of the dioxide. Hager found it in the earth, yet always in much smaller quantity than ozone. It appears to be markedly increased under a cloudy sky, and decreased under sunny days. Schönne further found that in July the amount is greatest, and gradually decreases until it finds its lowest, in January. According to Berthelot, peroxide of hydrogen undergoes a spontaneous decomposition into H_2O and free oxygen. He found that the decomposition occurred the more slowly as the solution became lowered in temperature.

Recent investigations, as those carried out by M. Miguel, of the Observatoire de Montsouris, appear to establish its claim as one of the most potent destroyers of bacterial life. He states that the smallest quantity of each substance capable of preventing fermentation in 1 litre (2.1 pints) of bouillon was as follows:

Hydrogen dioxide water	0.05 gramme.
Iodine	0.25 "
Bromine	0.60 "
Zinc chloride	1.90 "
Carbolic acid	3.20 "
Potassium permanganate	3.50 "
Boracic acid	7.50 "
Sodium salicylate	10.00 "
Borax	70.00 "
Absolute alcohol	95.00 "

According to the above list of bactericides and experiments, the dioxide of hydrogen is one of the most potent antiseptics and disinfectants yet discovered. It is as bland as water, when intelligently used.

Careful comparative tests with antiseptics now much in vogue prove it to be sixty times as powerful as carbolic acid, twenty times as strong as salicylic acid, and forty per cent. more potent than the solution of the bichloride of mercury. This is extraordinary, and may seem incredible, but experiments place it beyond a doubt. As a disinfectant it is superior to chlorine-gas or the fumes of sulphur. It oxidizes rapidly the offending matter, destroys it completely, and being decomposed into

water and oxygen, leaves no substituted odor in the place of the one removed.

The pure substance is one hundred per cent. strong, and yields four hundred and seventy-five volumes of gas. A one per cent. solution, then, is equal to a 4.75-volume solution. A fifteen-volume solution contains, therefore, a trifle more than 3.3 per cent. of the anhydrous hydrogen peroxide. A percentage composition of the pure substance reserves 5.88 per cent. of hydrogen and 94.12 per cent. of oxygen.

Dioxide of hydrogen of commerce is a solution of from 20 to 10 volumes, *i.e.*, a solution capable of evolving the quantity indicated of gaseous oxygen when fully decomposed. Thus, a ten-volume solution represents the following: 100 cubic centimetres evolve 1,000 cubic centimetres of oxygen, or, in other words, it contains 2.1 per cent. by weight of H_2O_2, and evolves 1.45 per cent. of oxygen by weight. Chas. Marchand, a French chemist, graduated from the "École Centrale de Paris," has prepared the best dioxide of hydrogen, which preparation I have used in all my experiments for the last two years.

For our knowledge of the physiological and therapeutical action of dioxide of hydrogen, the medical profession is indebted to Dr. W. B. Richardson, of London.

Directions for Making and Using Solutions of Dioxide of Hydrogen.—*Local use.*—Spray: 2 ounces 15-vol. peroxide of hydrogen for 14 ounces water. Gargle: 2 ounces 15-vol. peroxide of hydrogen for 14 ounces water. Irrigation: 3 to 5 ounces peroxide for 13 to 11 ounces water. Local use: 3 to 10 ounces peroxide for 13 to 6 ounces water. Inhalations: Full strength, 15 volumes. (Do not use any metal inhalers.)

Administration of ozonized vapor: Take two ounces of the 15-vol. sol., and add chemically pure glycerine, one ounce.

Internal use.—Dose of dioxide of hydrogen: From one to three teaspoonfuls of the 15-volume solution in one-half glass of water, three times daily, after meals. For diphtheria in children, without reference to age, two hundred parts of a 10-volume solution mixed with three parts of glycerine pure; a teaspoonful of this mixture every two hours, and in severe cases every hour.

MM. Paul Bert and P. Regnard were the first to recommend dioxide of hydrogen as an inhalation in phthisis. There is no doubt that the great field for the dioxide of hydrogen is by inhalation, for then we catch the nascent, just born, life-giving element peculiar to oxygen.[1]

I have constructed a special apparatus for the administration of ozonized vapor inhalations. This mode of treatment, by administration of ozonized vapor resulting from the decomposition of the dioxide of hydrogen, was used by me in eighty cases of diphtheria, for the most part "severe;" forty-two of which I operated on (intubated); of these twenty-seven died, and thirteen recovered. Of the thirty-eight not operated on, thirty-one recovered, and seven died; but of the latter four were already in a moribund state when called upon.

The fact obtained by experiment, that dioxide of hydrogen destroys the infectiousness of certain animal exudations, is of great value in support of the view of its similar action upon the diphtheritic exudation; and these facts have, for the most part, been established clinically.

The occurrence of oxidation can be shown by placing a piece of diphtheritic membrane in the dioxide of hydrogen, when there immediately occurs active effervescence with the liberation of oxygen, which attaches itself in small bubbles to the membrane without solution of the latter. By a longer action of the dioxide on fresh diphtheritic exudation in the living, the membrane takes on a more yellow or gray color, and fissures appear in it, after which its separation takes place. For the most part this occurs between the third and fourth day. Upon the general condition of the patients the effect of the dioxide was good, the appetite was notably increased, even when slight increase of temperature was present.

In diseases like tonsillitis and laryngeal phthisis it affords great relief; in chronic bronchitis with dyspnœa and in phthisis it operates favorably in the early stage by improving digestion and giving increased activity to the chalybeate remedies; while in the advanced stages it affords great relief to the dyspnœa and oppression, acting indeed, in this respect, like opium, without its narcotic effects; relieves the paroxysm of whooping-cough, and cuts short the disease more effectually than any other remedy. The ozonized vapor should be given in this disease every three hours for the first two to three days. Asthmatic paroxysms are relieved at once after four to five inhalations. In croup it will be found a very useful remedy. As a gargle in that terribly offensive condition of the breath that ensues when the secretion of the tonsils becomes cheesy and granular, in diseases of the nose, such as ozæna, nasal diphtheria, hay fever, syphilis, and ulcerated conditions, this remedy is pre-eminently indicated.

Ozonized vapor is produced from the peroxide of hydrogen by mechanical agitation, which produces its decomposition. A spray of peculiar shape is enclosed in an ordinary round bottle, and air passed through the spray-tubes in the same manner as in any ordinary one, with this only difference, that the spray is broken by being allowed to spray against the hard side of the glass bottle, and thereby the peroxide of hydrogen and glycerine become subdivided and decomposed into the minutest particles, and ozonized vapor is the result.

This ozonizer is made entirely of glass, which is one of the most important factors, on account of the powerful oxidizing effect which this agent possesses over metals of all kinds. Directions for using this apparatus are the same as for any ordinary spray. For the office it can be used in connection with condensed air, and for home use with the ordinary bulbs. The delivery tubes are made for up, down, and nasal administration.

The *modus operandi* of the peroxide of hydrogen is by yielding up and setting free one equivalent of oxygen, which, no doubt, is in a nascent and hyperactive state, leaving behind simple water. The difference in the peroxide of hydrogen and oxygen treatment is that the peroxide of hydrogen acts as the most active. I have applied a two-volume solution spray of the peroxide of hydrogen on a post-pharyngeal abscess, and found at once its powerful action; in comparison, I applied on other ulcerations oxygen-gas, and hardly any changes upon the ulcers were seen. The peroxide of hydrogen turns the ulcers perfectly white, and the decomposition of the pus and curative effect could be seen almost immediately. Peroxide of hydrogen should be kept at a temperature below 65° F.

It is not the purpose of this paper to more than call attention to a remedy which must, ere long, occupy an important place in the treatment of diseased conditions which has hitherto been tedious and often unsatisfactory.

New remedies and new applications of old remedies are introduced, which are accepted by the profession with a rush, as it were, and for a time become very popular, and then gravitate to their proper level, which, in some instances, is obscurity.

Hydrogen peroxide is worthy of careful study and investigation, and when accorded its proper place, it will occupy a high position on the list of our therapeutic resources.

91 Second Avenue.

[1] Charles Marchand's dioxide of hydrogen and apparatus for the administration of ozonized vapor, can be had from Ernest Drevet, 10 West Fourth Street, New York.

Professor Friedländer, the discoverer of the pneumococcus, who died two months ago at Meran, had been suffering for some time from pulmonary phthisis.

TOTAL PARALYSIS OF ALL THE MUSCLES OF THE LEFT EYE.

Optic Neuritis; Ptosis of the Lid; Paralysis of Accommodation and of the Iris (Traumatic).

By FRANK W. RING, A.M., M.D.,

ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, FELLOW OF THE ACADEMY OF MEDICINE, ETC.

Master C. B——, aged fourteen years, on July 9, 1886, while engaged in picking cherries from a tree, fell to the ground, striking face downward. The right side of the nose was lacerated, forehead cut, and he received a penetrating wound through the left upper eyelid about five millimetres above the inner canthus.

A physician was called, who cleansed and united the wound, closing the laceration over the left lid with sutures. The lad suffered intense pain throughout the night, and next day consulted Dr. Withers, of Paterson, N. J., who treated him up to July 16th. In this interval there was great pain, complete ptosis of the lid, immobility of the eyeball, and vision of the fingers at a few feet. There was also a discharge of pus from the wound. Dr. Johnson, of Paterson, was called in consultation. The wound was opened, an investigation made, with the astonishing result of the removal of a stick three inches in length and one-fourth of an inch in diameter. There was immediate relief of the intense agony the boy had suffered for a week, and slight increase in vision.[1]

July 28th.—There is complete ptosis of the lid; it is swollen, red, and œdematous, capable of no movement whatever. The eyeball is natural in appearance; complete paralysis of all the muscles; absolute loss of movement of the eye. Pupil slightly dilated, not susceptible to light. Vision limited to slight perception of shadows. Ophthalmoscopically, there are no marked changes. Blood-vessels good size, no tortuosity, slight œdema of the disk, with some grayish haziness. Complains of the unpleasant sensation caused by the drooping lid; no pain.

August 9th.—Assured that his vision is improving, as he can distinguish a bright light from darkness. There seems to be a very slight action to the superior and inferior recti. Prescribed a solution of strychnia, arsenic, and iron.

August 11th.—Had a consultation with Dr. C. R. Agnew. The optic nerve (papilla) seems whiter, vessels perceptibly diminished in size, changes in the retina. Lid is less swollen, but no decrease in ptosis. Has now visible increase in upward, downward, and inward movement of the eye. Dr. Agnew's prognosis for vision was grave; thought the muscles might regain their power, that there was an inflammation of the nerve near its exit from the orbit. The paralysis of all the ocular muscles was due to shock. From this date onward applications of the electric current were made to the paralyzed muscles with undoubted benefit.

August 25th.—Vision in right eye $\frac{20}{15}$; left, shadows of fingers in bright light. The ptosis is much less marked; can show the entire cornea by shutting the right eye. Inferior rectus turns the eye well downward and a little inward. Superior oblique not strong enough to control the inward movement of the inferior rectus. Action of superior rectus slight; internus, the same. Inferior oblique and externus, *nil*. The nerve is much whiter, but the vision decidedly improved. Counts fingers readily.

September 13th.—The improvement since last date has been slow, but decided. The ptosis now lacks three millimetres of normal position. The externus has two thirds its normal power; superior rectus, three-quarters. The other muscles, with the exception of the internus, are quite as powerful as ever. Stopped the electricity. Gave biniodide of mercury and general tonic. No improvement in vision. The iris has continued in semi-dilated state, with no response to light.

February 22, 1887.—The vision has not improved to any marked degree during the last three months. From fingers at two feet, he now sees $\frac{6}{200}$. There is slight ptosis. A divergence from insufficiency of the internus, not disagreeably marked. The pupil semi-dilated and fixed. The nerve is bluish-white, blood-vessels of retina decreased in size. Has had no pain and little discomfort from loss of vision. The right eye has $\frac{20}{15}$ + Hm. .75. General condition excellent.

In all the ophthalmic literature on wounds of the orbit and paralysis of the ocular muscles, consulted by me, I have been unable to find a case of equal interest with the above. That a stick three inches long should penetrate the orbit, and remain undetected for a week is not so remarkable. Several instances have occurred where larger foreign bodies than that have remained undiscovered back of the eye, in the cellular tissue, and even penetrating into the brain; but I can find of none occurring where the ultimate result of such an injury was attended with so little calamity.

Injuries to the ocular muscles are quite rare, owing to the manner in which they are protected. The eyeball, resting as it does upon a soft cushion of connective tissue and fat, is in the case of penetrating wounds pushed aside. The recti muscles, being behind and converging to the apex of the orbit, as also the third and sixth nerves entering their substance on the inner surface, are both equally guarded.

The question arises: How can a lad, fourteen years of age, dispose of a stick three inches long and one-quarter inch in diameter, which has entered his orbit at the nasal supra-orbital ridge of the frontal bone, and left no visible trace of its existence? The shape of the cavity being that of a cone, one would suppose it would naturally seek its apex, passing through the sphenoidal fissure into the middle fossa of the base of the skull, and bringing up against the petrous ridge of the temporal bone, disturbing in its course the optic nerve, third, fourth, and sixth cranial, besides the fifth and superior maxillary, also the meningeal and carotid arteries, besides causing a shock and surprise to the middle lobe of the brain.

The symptoms of the injury might contraindicate such a disposition of the foreign body, yet it is the easiest way in, and may very likely have happened.

The nasal and cranial portions of the orbit are formed by bones of extreme thickness. The stick may have passed through the ethmoid into the vault of the pharynx. It may have been deflected through the spheno-maxillary fissure, which would have caused a protrusion of the eyeball and unpleasant mastication, symptoms which did not exist. We might infer that the cherry-twig may have bent in its course, but a piece of wood of such a diameter is not liable to curve in the loose areolar tissue of the orbit.

The antero-posterior diameter of the orbit of an adult skull lying before me is two and one-eighth inches. From the supra-orbital ridge to its apex is a little less. The preceding surmises in regard to the probable course of the stick are based upon measurements of this adult skull. The orbit of a boy fourteen years old would necessarily be less, leaving over one inch of wood unaccounted for.

The optic neuritis and paralysis of all the muscles can be accounted for in various ways. Extravasation of blood into the cavity of the cranium, which would also cause a paralysis of the opposite side of the body. Effusion of blood into the orbit. Shock, as suggested by Dr. Agnew. Direct violence to the nerves, as a passage of the stick through the sphenoidal fissure. Complete paralysis is usually owing to some cerebral lesion. Had there been much of an effusion of blood into the orbit, we should have had considerable exophthalmos, and there was little or none.

Wounds into the cranial cavity are almost always fa-

[1] The preceding history was gathered from the patient and his family. Dr. Johnson has informed me that he will report the case, giving more minute detail of the operation and symptoms up to the time the lad came under my care.

tal. The most remarkable case on record that I have been able to find is that reported by Percy, of a man who received a sword-thrust into the orbit, penetrating *six inches* into the cranium. The piece was extracted, and the man lived—a week. An Englishman ran against the end of an umbrella while walking on a stormy night. He consulted a doctor, who sent him home with the brass ferrule of the umbrella in the orbit undetected. Twelve hours afterward he suddenly died, and two inches of brass was found sticking through the orbital plate of the frontal bone. Caution should be used in the prognosis of a penetrating wound of the orbit.

Sword-thrusts through the orbit are not uncommon, but death almost invariably follows. Dr. Roe reports a case of a pitchfork plunged into the orbit, with no loss of vision, but paralysis of one side. The fact of Paré extracting the end of a broken lance from the orbit of the Duke of Guise is a well-known anecdote.

A laborer struck a co-worker with a lath, driving a piece of wood two and one-half inches long through the inner wall of the orbit. He recovered, with the use of the ocular muscles and perfect vision, which might have happened to Master C. B—— had the cherry-branch gone into the pharynx.

An importunate beggar was unreasonably soliciting alms from an Italian nobleman, whereupon he struck the beggar with a fan. Three months later a piece of the fan, three inches long, not previously detected, was removed through the palate.

Dr. Roswell Park reports, in "Knapp's Archives," a case of severe injury of the orbit, where a piece of wood from a revolving saw flew into the eye, perforating the lower lid, causing diminished tension, cloudy cornea, contracted pupil, etc. Five months after the injury a section of pine-wood, two and one-half inches long and one-half inch square at its base, was removed. It had been driven through the inferior exterior wall of the orbit, lying partly in the cavity and partly in the zygomatic fossa.

Dr. Knapp reports a case of coal-gas poisoning where there was paresis of all the muscles, also of accommodation. Recovery, with a tenotomy of the externus, four and one-half months later. Cases of paresis from diabetes are also reported.

It seems to me from the preceding cases referred to, and other literature on the subject, that the case in question is unique, and one of considerable importance. Inasmuch as the sight has not improved for some months, the probability of any further increase in vision is very doubtful. The strabismus from insufficiency of the internus will become greater in time, as is usually the case with amblyopic eyes. The ptosis, now slightly marked, will improve.

101 Park Avenue.

Sepsis and Antisepsis in Summer Diarrhœa.—Dr. S. A. Potter writes: "Will you allow me to rectify a statement made in my article on 'Sepsis and Antisepsis in Summer Diarrhœa,' published in The Medical Record of July 9th, relating to the time required to sterilize a fluid by boiling. The time mentioned is too brief. Fraenkel states ('Grundriss der Bacterienkunde,' second edition, p. 80) that the exposure of fluids to constantly renewed steam, as in the steam sterilizer of Dr. Koch, for about thirty minutes suffices to thoroughly sterilize them. In his directions for sterilizing bouillon for culture media, however, he recommends that the fluid be exposed in the steam sterilizer for three-quarters of an hour, and that the same process be repeated on two or three consecutive days. Klein, in his 'Micro-organisms and Disease,' third edition, page 19, gives similar instructions for sterilizing bouillon. Evidently, when the practical matter of rendering fluids sterile beyond doubt is concerned, the application of the temperature of boiling water for a very considerable length of time is required."

THE CLIMATE OF ALBUQUERQUE, N. M.

By THOMAS J. CUMMINS, M.D.,

ALBUQUERQUE, N. M.

The object of this paper is to present a few facts concerning the climate of a section of this country which has been, until the last few years, a veritable *terra incognita* to the physician, as well as the public generally through the country. This lack of information can be easily accounted for when the fact is known that until the advent of the railroad, some six years ago, this region was practically inaccessible to travel. To-day this is all changed. The old Spanish régime of the past, with its wealth of interesting legends and traditions, has yielded to the more progressive and practical spirit of modern times. Albuquerque is an excellent illustration of this change. The new town, which has risen into existence within the past few years, contains a large population of enterprising people, enjoying all the benefits of city life, such as churches of all denominations, excellent schools, good society, streets lighted by gas and electricity; a good system of water-works, supplying an abundance of pure water; also, well-conducted hotels and boarding-houses. All this gives the city the appearance of an eastern town, and causing the invalid in search of health to feel that he has come to reside in a community of progressive and intelligent people, and not, as is vaguely hinted at and believed, of the lawless and ignorant.

With these remarks as introductory to the main purpose of this article, I will proceed to state a few facts concerning this region and its climate, which may prove of interest to the medical profession. It may be well to call attention to the vast area comprised within the borders of the territory, covering as many square miles as the whole of New England with the States of New York and Maryland added. Its mountains and valleys furnish almost every variety of climate, from the warm and salubrious to the cold and invigorating, the peculiar character of each being a remarkable freedom from moisture, unequalled probably by any other region of this country or Europe. Albuquerque is situated in the central part of the territory, in the fertile valley of the Rio Grande, and at an altitude of 5,000 feet. It is sheltered on the east by a high range of mountains, towering to an altitude of over ten thousand feet; on the west a low ridge of mountains completes the formation of the valley. The latitude of this region is about the same as that of Santa Barbara, Cal.; Memphis, Tenn.; Algeria in Northern Africa, and the Mediterranean Sea.

The profession already recognize the important therapeutical effect exerted by a suitable climate in many chronic diseases, especially in those suffering with chronic pulmonary phthisis. The natural factors considered by all writers on climatology as being necessary for the successful climatic treatment of phthisis are all present here in rather a remarkable degree, namely, extreme dryness and purity of the atmosphere, abundance of sunshine, and high altitude, combined with the necessities and comforts of life. The absence of this last factor has discouraged many invalids in the past from seeking a residence in this climate. This objection no longer holds good, as will be presently shown.

Many other features are dwelt upon by climatologists as being of more or less importance, such as a dry, porous soil; electric condition of the atmosphere, with its natural product, abundance of *ozone;* also a plentiful supply of pure water. That many, if not all, of these qualities are present here in a greater or lesser degree, I will endeavor to demonstrate from personal observation and the "United States Signal Service Reports."

Dryness and purity of the atmosphere.—The geographical location of this region of the Rocky Mountains is such as to exclude the possibility of the presence of moisture from either ocean, or any other large body of water. This relative dryness is present here to an extent un-

equalled by any region on this continent, with the exception of some stations in Arizona. The air is so pure and clear that our perception of distance seems to be almost annihilated, the mountains, some twenty miles to the east, appearing only two or three miles distant. The most convincing proof of the dryness and purity of the air is its peculiar antiseptic property. Flesh does not decompose when exposed to the air, but is preserved for an indefinite length of time through becoming *desiccated* by water-abstraction. The bodies of animals dying on the plains about here dry up, becoming mummified. May we not have, here, the ideal long sought for by every surgeon—a pure *aseptic* atmosphere, entirely free from germs? The so-called rainy season occurs in August and September. It must be understood that it does not rain continuously during these months, the rain generally coming on in the afternoon, in sharp showers of rather short duration, imparting a refreshing coolness to the air and moistening the dry, parched earth, which quickly absorbs the most copious showers. I failed to observe a single day of continuous rain. Bright, sunny skies, some portion of the day, were the rule even during this season; two or three pleasant days often intervening between the showers. The past winter was extremely mild, and almost free from snow and rain. The severe snow-storms which visited most sections of the country during last November were scarcely felt here. In fact, the ground has not been covered with snow a single day during the past winter.

Dr. Tyndale, in his work on the treatment of consumption,[1] makes the following observations in relation to the important factor of dryness, or absence of excessive humidity: "The degree of moisture which we would like to have as one of our factors is one just sufficient to keep the land from becoming a desert; or, in other words, no moisture brought from large bodies of water, near or far, and only a limited rainfall throughout the year."

After considering the climatic advantages of the different regions throughout the country, this writer observes that "New Mexico and Arizona are only beginning to be sufficiently civilized to furnish, in addition to the ideal factors lavished upon them by nature, the lesser factors relating to comfort and ready communication with the rest of the world. But I want you to remember this section as one of future centres of ideal climate for consumptives."

"The lowest death-rate from diseases of the respiratory system, as shown by the medical statistics of the United States army, is in New Mexico.[2] Hammond's 'Hygiene' testifies to the fact that 'New Mexico is by far the most favorable residence in the United States for those predisposed to, or affected with, phthisis.'"

Abundance of sunshine.—This important element is present here to an extent unequalled by any other inhabitable section of this country. Daily personal observations during the past seven months result in a record of only *four* entirely cloudy days throughout that period, demonstrating conclusively the claim this region possesses of being a land of almost perpetual sunshine.

Its therapeutic value in the treatment of consumption is acknowledged by all writers on the subject—its presence rendering it possible for the invalid to remain out-doors every day, and at almost any hour of the day, allowing abundant time for valuable exercise in walking, riding, or driving; it even being extremely comfortable, throughout the winter months, to sit out-doors many hours of the day and enjoy the luxury of a mid-winter sun-bath. Unfortunately there is no meteorological record of the climate of Albuquerque to present for comparison with other sections of the country, the nearest Signal Service station being located at Sante Fé, some sixty miles north of here, and at an altitude of *two thousand feet* above this valley.

[1] Home and Climatic Treatment of Pulmonary Consumption, by J. Hilgard Tyndale, M.D. 1882.

[2] Smithsonian Institute Report. 1876.

The temperature-record is much lower during the winter months than that of Albuquerque, registering eight degrees *below* zero early in January, while I failed to observe a lower marking than twelve degrees *above* zero the coldest day this winter.

The only other stations of the Signal Service in the territory are over two hundred miles south of here, at Silver City and La Mesilla.

Judging even from the incomplete record furnished of this latter station, it appears that the climate of La Mesilla approaches nearer to that of Albuquerque than the colder and higher altitude of Sante Fé.

In selecting statistics from the "Signal Service Report" I have chosen a representative city of the different sections of the country having a reputation as a "health-resort" for the climatic treatment of phthisis, for comparison with the meagre record at hand for this vast territory.

I also append statistics of a few of the large cities of the East, deeming it advisable to compare the climate in which phthisis is contracted, or developed in those having an hereditary predisposition to the disease, to a region possessing a climate which approaches nearer to the *ideal* for consumptives than any other of which we have record.

	Altitude.	Mean annual temperature, in degrees F., from July, 1880, to June, 1881, inclusive.	Mean annual humidity, in degrees F., July, 1880, to June, 1881, inclusive.	Mean annual precipitation of rain and melted snow, amount in inches, July, 1880, to June, 1881, inclusive.	Number of days with .01 inch or more of water, July, 1880, to June, 1881, inclusive.		Number of days in 1884 which were:			Average hourly velocity of the wind, in miles, for 1884.	Average hourly velocity of the wind, in miles, for March, 1884.
					Rain.	Snow.	Clear.	Fair.	Cloudy		
Santa Fé, N. M....	7,046	45	45	9	48	18	156	169	46	7.1	8.1
La Mesilla, N. M..	4,124	59	41	7	37	3	[1]	..	..	..	..
San Diego, Cal.....	67	58	72	10	48	0	122	157	85	6.0	6.5
Jacksonville, Fla...	43	70	71	65	127	0	124	156	85	6.6	7.9
St. Paul, Minn.....	811	44	69	29	82	50	96	160	110	8.3	8.8
San Antonio, Tex...	676	67	73	41	113	0	[1]	..	..	4.7	4.9
Boston	142	49	66	37	104	15	103	124	128	9.2	11.3
New York City.....	164	52	70	37	123	12	99	153	111	9.4	11.6
Philadelphia.....	52	54	67	33	112	15	109	150	98	9.7	11.8
Chicago	661	50	67	37	112	31	107	124	108	8.4	9.7

Comment on these reports[2] is unnecessary. I would draw especial attention to the small rainfall at San Diego, and the excessively large mean annual humidity, exceeding that of the large Eastern cities and that of Jacksonville, Fla., where the rainfall is six times as great as in San Diego. St. Paul, Minn., has been considered as having a cold, dry climate, with a mean humidity of 69° and 132 days on which rain or snow fell; the important factor of dryness appears sadly deficient, as does that of San Antonio, Tex., when compared with the stations in New Mexico. My statements in relation to abundance of sunshine are substantiated by these reports, La Mesilla having only 40 days on which rain or snow fell, the smallest number of any station I have selected, and the nearest approach to the record of Albuquerque that I have been able to estimate. Jacksonville, Fla., with an annual mean humidity of 71° and rainfall of sixty-five inches, is an excellent example of the warm, moist climate to which consumptives were sent before the study of climatology had received much attention. This brings me to the consideration of the *high-altitude* treatment of pulmonary phthisis. Professor Loomis[3] says, that "altitude is regarded by many at the present time as of more importance than any other natural element," and mentions, "Davos am Platz, in the Swiss Alps, has been most extensively visited. Williams, Albutt, and other English physicians give very favorable reports of it. It is 5,200 feet above the sea, very dry,

[1] No record.

[2] Report of the Chief Signal Officer, War Department, 1881, and Part I., 1885

[3] Practical Medicine, by A. L. Loomis, M.D. 1885.

but not windy and not changeable. Davos possesses, also, the unique climatic characteristic of freedom from high winds (the records showing that from October 1, 1880, to March 31, 1881, there were one hundred and thirty-four days with 'no wind'), while its 'sun temperature rises even in January, as Dr. Franklin notes, as high as 150°, conditions which admit of much invalnable out-door exercise by invalids. Doubtless some high winter resort, combining these vitalizing conditions, can be found in the Southwestern Rocky Mountains of our own country." I quote Professor Loomis at length, believing his description of the winter climate of Davos almost identical in every particular with that of Albuquerque, N. M., excepting the intensity of "sun temperature," which ranged from 85° to 100° many hours of the day during December and January. Regarding the prevalence of high winds, so common at elevated stations, and which so severely try the weakened vitality of the ordinary consumptive, I would say, from my own experience, from October 1, 1886, to March 4, 1887 (at present writing), I have recorded only six days, all in February, on which the wind blew with sufficient velocity to be uncomfortable. By referring to the Signal Service reports it will be seen that the annual hourly velocity is less, by two miles an hour, than in Boston or New York City; while for March, which is the most disagreeable month of the year in Albuquerque, as in many other sections of the country, the velocity of the wind is three miles an hour less than at sea-level.

Owing to the dry, sandy condition of the soil, a moderately high wind will blow particles of sand and dust about in a manner which, to say the least, is disagreeable. These "sand-storms" come on suddenly in the afternoon, and continue on through the day, and even night. My experience of them is rather limited. The natives say they purify the atmosphere. I will not venture an opinion *pro* or *con*, but would state that a warm, dry wind, containing particles of sand and dust is less injurious and more easily borne by a consumptive than a cold, penetrating wind laden with moisture from the ocean or any other large body of water. The disagreeable effects of the former can be readily removed from the surface by repeated ablutions, but the deep-seated effects of the latter yield less kindly, demanding more heroic treatment. The interesting investigations of climatologists detailing the effects of high altitude upon the human economy can only be briefly referred to in this hastily prepared paper. The "line of approximate immunity" in Switzerland was found to be at five thousand feet. I have seen a well-marked case of phthisis in a young Mexican of the poorer class, which ended fatally. Their mode of life is conducive to it, living as they do in low *adobes*, with little or no ventilation, often overcrowded and lacking the proper quality and quantity of food. With these anti-hygienic surroundings no arbitrary "line" is sufficient to fix the bound of immunity.

The barometric pressure is diminished one-fifth at an elevation of six thousand feet, relieving the surface of the human body of a pressure of three pounds to the square inch, and causing an acceleration of the heart's action and rapidity of the function of respiration until the system accommodates itself to the change, which eventually it readily does, as shown by the increased strength of the heart's action and the permanent enlargement of the circumference of the chest.

The diurnal range of temperature in mountain-regions is greater than at sea-level. Equability is too often accompanied by excessive moisture. The dry, rarefied mountain-air permits a great daily range of temperature which, though thermometrically great, is sensationally small. The nights are always cool, even during summer, blankets being necessary for comfort. This leads me to refer briefly to the factor of *necessities* and *comfort* of life.

The markets are well supplied at all seasons with fresh meats of all kinds, and vegetables and fruits in their season. By means of an extensive system of irrigating canals, called *acequias*, the soil yields richly to cultivation. Peaches, plums, apricots, and many other varieties of fruits are raised here.

Grape-culture receives great attention from the natives. An excellent variety, called the "Mission" grape, is extensively cultivated here. A very good quality of "native wine" is made from this grape. The neighboring mountains are much resorted to during the summer months, a few hours' drive bringing you into one of the many cañons found within their limits. Time will not permit me to even mention the many medicinal and hot springs located in the surrounding mountains.

The intention of this paper being merely to call attention to a climate which has only to become known to be better appreciated, I feel that my duty is done. The usually prescribed residence of three or four months will accomplish but little toward a permanent relief or arrest of the phthisical process. A residence of two or three years does and will accomplish great results. Professor Loomis says, in his work on "Diseases of the Respiratory Organs:" "In whatever locality a phthisical patient finds himself improving, it is important that he remain in that locality so long as he continues to improve."

Indications for adopting the high-altitude treatment of phthisis.—The London Lancet,[1] in an article on this subject, prints the following suggestions: "The cases that do best at high altitudes are those of simple phthisis in patients who are free from cardiac, renal, or rheumatic complications, and who exhibit a torpid reaction to the disease. Cases of chronic and stationary phthisis, with slight constitutional disturbances, are likely to react favorably to the stimulating properties of the climate of high altitudes. Also cases of delayed convalescence from pneumonia and fibroid pleurisy. Hemorrhage is rare at high altitudes, even in those who suffer repeatedly from it while resident on the plains."

Contra-indications to high altitude.—"When high temperature, rapid emaciation, and much prostration indicate profound constitutional disturbance, we may conclude that mountain-treatment is inapplicable. Organic nervous diseases, marked functional nervous excitement, especially hysteria, and persistent sleeplessness prove strong contra-indication to high altitudes."

I consider this an excellent summary, from my rather limited period of observation, of the cases of phthisis benefited by the high-altitude treatment. Advanced third-stage cases do badly, not having sufficient vitality to accommodate themselves to the increased demand placed upon the already weakened and overburdened heart and lungs. The system fails to react favorably to the stimulating properties of the climate, death coming to the relief of the patient, whose life might have been prolonged a few weeks, or months, had wise counsel prevailed, and home comforts prescribed instead of change of climate.

Before concluding, I shall take the liberty of quoting Professor Loomis once more concerning the climatic treatment of phthisis: "My most decidedly beneficial and permanent results have been obtained (when the evidences of consolidation were present) in Asheville, N. C.; New Mexico, and the Adirondack region in New York State." That New Mexico is becoming favorably known and recommended, in preference to many other sections of the country, is evident from the indorsement it receives from many prominent physicians in the East. I have been personally advised to reside in this climate for the relief of a slight consolidation of the lung by such recognized authorities as Drs. A. L. Loomis and J. E. Winters, of New York, and Knight, of Boston. I have examined a patient with consolidation of the apex of the lung, sent here by Dr. E. G. Janeway, of New York. Mention is made of these physicians to show what members of the teaching faculty of three of our most prominent medical colleges advise in the important matter of the climatic treatment of pulmonary phthisis.

[1] The Lancet, October 30, 1886, MEDICAL RECORD, December 25, 1886.

Clinical Department.

A CASE OF COMBUSTION.

Dr. George O. Williams, of Greene, Chenango County, N. Y., reports the following post-mortem examination, made twenty hours after death, on a youth, aged eighteen years: "He had had dinner at noon. The body was found at 2 P.M., lying on the dry plank-floor of a stable, feet on the threshold of an open door. The clothing inventoried, pair of cotton pants and overalls; one, possibly two, cotton shirts, shoes and stockings. Estimated weight, minus shoes, four pounds. All the clothing was consumed except fragments on the ankles and one shoulder; these were still burning without flame when discovered. An edge of the plank on which the body lay was charred for six inches, and, at one point, a small flame appeared. The surface of the plank beneath the body was slightly browned for a diameter of twelve inches. The skin, even on the face, was deeply burned—cooked—fully one-half the surface of the body was deeply browned in large detached areas. On these areas were gaping fissures in the skin, four to twelve inches long, exposing roasted fat, and in some places muscular tissue. The fissures in the flexures of the thighs and knees were deep, and the exposed tissues tender. The genitals were charred, the foreskin crumbly. On making a section the tissues felt, under the knife, and looked, like any roasted flesh, even to some extent on the internal thoracic walls. A cartridge ball had traversed the upper and lower lobes of left lung, the right ventricle, and left auricle. Coagula filled the thorax. The lungs were collapsed. The lad had taken whiskey during the forenoon, quantity unknown. His habits were reported to have been somewhat unsteady. The query arose, why should the body have been so extensively and deeply cooked with the limited amount of fuel, and at the same time the dry planking beneath it be so trivially damaged? A theory was suggested that the body was rapidly exsanguined by the wound, and, after ignition by the exploding cartridge, the slowly burning cotton fibre melted and absorbed the subcutaneous fat, which, aided perhaps by alcoholic saturation, furnished additional heat necessary to produce the effect."

COOL BATHING IN INFLAMMATORY BOWEL AFFECTIONS OF CHILDREN.

Dr. E. G. Comegys, of Cincinnati, O., writes: "Ten years ago I published an article in The Medical Record representing the great value, to children suffering with enteric congestion and inflammation, of cool immersion baths, and a colder affusion meanwhile to the head. The prompt and radical change for the better by this treatment is something delightful to behold. I wonder if any of your physicians are trying this method in the wide-spread summer complaints that are now so prevalent in your tenement-house districts. It is very easily applied, but in every case the physician must show how it is done. A tub of hydrant water, at 90° F. (if the fever be very high, 85°), is to be used. The infant should be gradually wetted before the body is fully immersed, for the sudden application of cool water is very distressing. The head is to be held in the left hand, while with the right an abundance of colder water, at, say, 65° (the usual temperature of cistern water), is poured in a steady stream over the forehead and scalp everywhere. Ten to twelve minutes should be employed in the operation, or not so long if the sedation seem sufficient. I generally wait until the lips get bluish, and the jaw quivers. Envelope the child unwiped in a woollen shawl, and lay it on the bed. Reaction will soon come on, with sweating, and a sleep of the sweetest kind will follow, with cessation, commonly, of all fever, vomiting, and diarrhœa; in fact, a convalescence is set up. The patient is usually excessively thirsty, and will drink greedily of the colder water you are applying to the head; let him have it abundantly. Afterward, it is a question of better air and appropriate food. This sudden and healthful change is seen especially in the congestive forms which are hastening on to positive inflammation; as it is, the mucous and serous membranes are suffering, brain as well as the rest; so you have the sero mucous, green, pultaceous stools; the insomnia with headache, contracted pupils, and ataxic state of the motores oculi; the pulse is rapid and weak, and the respiration hurried and superficial; yet the fibrinous effusion has not taken place, but it is just at hand. This very alarming condition is usually thoroughly and speedily overcome by a cold bath. It is a condition of general vaso-motor paresis, which is so readily overcome by the cutaneous treatment. If inflammatory action has taken place, of course so sudden a convalescence cannot be brought about; then more bathing, and further use of appropriate remedies must be used. I make no reference in the above to so deadly a disease as cholera infantum. This is often as suddenly fatal as Asiatic cholera. The vomiting and diarrhœa must be checked by an appropriate hypodermic injection of morphia, with the immediate dosing of calomel, so as to secure a cholagogue action by the time the restraining effect of the morphia passes off."

CARBOLIC-ACID INJECTIONS IN THE TREATMENT OF CARBUNCLE.

Dr. John B. Richardson, of Louisville, Ky., writes: "In the Louisville *Medical News* of June 25, 1881, I published an article under the caption of 'Carbuncle—its Treatment,' contrasting the old, and then generally practised method in cases of carbuncle, and giving in detail my method of treating it with parenchymatous injections of carbolic acid, assigning as reasons therefor its mode of action, its lessening the area of destroyed tissues; by its employment avoiding the use of the knife; its causing immediate mitigation of pain; its preventing the danger of blood-poisoning; and its materially lessening the duration of the affection. Concerning the action of this remedy I use this language: 'The carbolic acid (injection) has the effect of stimulating the circulation of the parts involved in the diseased action with which it is brought in contact, thus enabling them to repel this tendency to sloughing. It acts as a local anæsthetic, together with the external application of belladonna, removes to a great extent the usual necessity for the internal administration of sedatives to obtain sleep and lessen pain. . . . The antiseptic and antiputrefactive qualities of the acid reduces the danger of pyemic symptoms to a minimum.' As to the mode of using these injections I wrote: 'When first seen and recognized to be a carbuncle in its formative stage, make a small opening with a sharp pointed bistoury in the centre of the swollen and inflamed structures just large enough to allow the easy introduction of the nozzle of a hypodermic syringe, which has been previously charged with a fifty per cent. solution of carbolic acid in oil or water, and after passing it a short distance into the central forming slough, press the piston sufficiently to expel a drop or two of the contents of the syringe; retract and deflect the point of the syringe as you reintroduce, and repeat this until you have insinuated the solution into a considerable area of the interior of the commencing carbuncle.' I have noticed lately in several medical journals—The Record, among others—that Dr. Bidder, of Berlin, recommends the treatment of furuncles by the parenchymatous injections of carbolic acid as something novel and generally untried. Since 1879 or 1880, I have not only used carbolic-acid injections to the exclusion of all other methods of treating carbuncles and furuncles—and published my article, above mentioned, in 1881—but have advised many of my professional brothers that this treatment with hypodermic injections

of a solution of carbolic acid within the parenchyma of carbuncles and furuncles was far superior to any other mode of treatment yet suggested. I write this only with the view of keeping the credit which belongs to America on this side of the Atlantic, where it originated and belongs. It is the best manner of treating carbuncles and furuncles yet proposed, doing away with—as I hope, forever—the useless, painful, and unnecessary destruction-of-tissues procedure caused by crucial incisions."

POISONING FROM A SPIDER BITE.

Dr. G. W. Squires, of East Avon, N. Y., reports the following case: "Lula B——, aged twenty, while in the garden, felt something crawling on her neck, and before she could brush it off was stung. The pain was so intense that she nearly fainted. She hastened to the house, and before the cause of her trouble could be found was bitten again on the opposite side of the neck. The mother found a small, white, soft-bodied spider, which when crushed emitted a sickening odor. The girl almost immediately felt dizzy, sick, and prostrated. The pupils were widely dilated, the tongue was thick and swollen, there was constriction of the throat, difficulty of swallowing, with a sense of impending strangulation. She complained of her head feeling large, of flashes of light before the eyes, and of lancinating pains all through her body. In ten minutes the neck was greatly swollen, and the heart labored as from a severe shock. It was with great effort that the patient could keep awake. Strong tincture of iodine was immediately applied to the bites, and stimulants were given internally. The application seemed to stop further absorption of the poison, but only after three hours was the patient able to sit up, and she felt poorly for several days."

SECONDARY HEMORRHAGE FOLLOWING UVULOTOMY.

Dr. G. B. Hope, of this city, reports the following rare case: "T. H——, aged twenty-seven, applied for treatment for chronic catarrh affecting the nose and throat, at the Metropolitan Throat Hospital. The patient was of slender figure and pallid complexion, but had no organic lesion of the heart, and gave no history of a hemorrhagic disposition. An exostosial formation in the left nostril, extending some distance from the triangular cartilage along the vomer-maxillary articulation, impeding both drainage and respiration, was removed with the Goodwillie drill. It was noticed that the bleeding during the operation was more free than usual. The uvula, being considerably elongated as well as hypertrophied, was excised two days later. The redundant portion only was removed with the scissors and forceps, leaving the muscles intact and the organ of a normal length and appearance. The hemorrhage was rather free, but was checked by a few mouthfuls of cold water. Three days later cicatrization seemed to be well advanced. Eight days after the operation the patient called to report that severe hemorrhage had taken place for the first time, at intervals, during the preceding night. The bleeding was controlled temporarily by an astringent gargle, but returned repeatedly. Inspection of the mouth revealed a large clot adhering firmly to the tip of the uvula, and drawing the organ aside provoked a return of the bleeding. The hemorrhage was purely venous, but so abundant as to prevent the effectual employment of the galvano-cautery, and exceeded by measurement a drachm a minute. The uvula was seized between the blades of a pair of long dressing-forceps, and the bleeding vessel was grasped by an artery-forceps and twisted. The cut surface was found to be sloughy throughout, and without any appearance of cicatrization. Four days later the wound had completely closed. The ease with which the hemorrhage was arrested in this case would show that it would not be necessary, in a similar emergency, to resort to any other means than that of astringent applications, or to the galvano-cautery. Hemorrhage after uvulotomy is one of the rarest complications, and at the Throat Hospital, where the operation has been practised upward of nine hundred times, not a single history of troublesome hemorrhage appears. Nevertheless, two unreported cases, which have recently come to my knowledge, go to show that even this minor operation is not to be undertaken without due caution. So far as I am aware, no other instance of a secondary hemorrhage occurring later than the second day has been recorded."

THE CAUSE AND RATIONAL TREATMENT OF CHRONIC BRONCHITIS.

Dr. Alfred W. Perry, of San Francisco, Cal., sends us the following communication: "Bronchitis is most frequent in cool climates in which the humidity of the atmosphere is seventy per cent. or upward. Neither a cold, dry air, nor a moist, warm one, will cause bronchitis. To act powerfully in producing the disease, the atmosphere must have a temperature below 65° F., and its humidity must be seventy per cent. or over. The most damp climates in the United States are those of New York, New Orleans, and San Francisco, which have a relative humidity, respectively, of 76.5, 71, and 73.2 per cent. during the six cooler months, and 76.5, 71, and 78 per cent. during the warmer months; and a mean temperature of 42.5°, 64.4°, and 54.5° in the colder months, and 65 5°, 78.5°, and 57° during the six warmer months. The driest climates are Denver and El Paso, with a relative humidity of 46.6 to 60.5 per cent., and 30.3 to 40.8 per cent., respectively, in the six cooler, and the six warmer, months of the year.

"Chronic bronchitis tends naturally to recovery, as may be evidenced by the remissions which occur in summer. After a first attack of bronchitis in a cool, moist climate, the succeeding attacks last longer, until a chronic condition is reached. It is not the original attack which has gradually increased to this condition, but it is the sum of the many little damages left from each of the subsequent attacks. This fact points to the principal indication, viz., the prevention of subsequent attacks. This is not so difficult as it may seem, provided the details of a treatment, neither expensive nor offensive, are carried out. These subjects get a coryza on the slightest exposure, and this inflammation travels down the respiratory tract to become a bronchitis. Sponging the upper parts of the body with cold water daily on rising will remove this excessive susceptibility. Cold showering of the upper part or the whole of the body is still better, when it can be borne. These patients should rarely take a very warm bath, and then only before retiring. When the weather turns cool suddenly, or is foggy or rainy, and at night, they should, on going out, wear a wire-gauze respirator, which will cause them to breathe a warm air. The English respirator is a covering for the mouth, consisting of fifteen or twenty layers of fine gilt brass wire gauze. By arranging a respirator so that every expired breath passed through it, and the inspired air passed through the respirator and then into a chamber containing a thermometer, I found that air of 60° was raised to 70°, that of 50° to 61°. The temperature of the expired air from the lungs is about 85°, and this heats the wire gauze to nearly the same temperature, and this in turn warms the inspired air. Raising the temperature of air from 60° to 70° decreases the relative humidity forty-three per cent., and raising it from 50° to 60° decreases the relative humidity twenty-eight per cent. It follows, therefore, that, by the use of a respirator in the cold, damp weather found in New York or San Francisco, we can, in effect, cause the patient to breathe an air as dry as that of Denver or El Paso, and of an agreeable warmth. Of equal importance in the treatment of chronic bronchitis is the maintenance of a moderate irritation for months. The preference, in the case of young and middle-aged persons, is a solution of from

five to fifteen per cent. of croton-oil in ether, with a little tincture of iodine to color it. This is known as Corson's paint. One application with a camel's-hair pencil will usually cause a copious eruption of papules or pustules. In the aged this seems to have no effect, and in such cases nothing is so good as small fly-blisters. These applications should be made three or four times a month. I have said nothing about the use of sedative and stimulant expectorants, for they are of slight utility. The only internal medication which I have found of much benefit is the use of bitter mineral tonics, of which the phosphates of iron, quinine, and strychnine (Aitken's formula) is a type. Several different mixtures of phosphates and hypophosphites have given me excellent results in chronic bronchitis."

EFFECTS OF A FRIGHT.

Dr. G. W. Squires, of East Avon, N. Y., reports the following case: "Cora W——, aged twenty one, met with a peculiar accident or fright two years ago, from the effects of which she has never recovered. She was asleep in bed when, about midnight, a large piece of plaster, about one yard square, fell from the ceiling over her bed, striking her on the face and body. She awoke in a terrible fright and fainted away, but at last succeeded in getting down-stairs. She aroused her parents, but was trembling like a leaf, and could not speak to them. Before the fright her pulse was 75 to 80 per minute; the next morning it was found to be 135, and has remained at that rate ever since. Medicine appears to have little effect upon the heart to lower the pulse. The girl before the accident was a quiet, healthy person, but is now quick and nervous, starting at the slightest sound, and constantly in fear of being frightened. The heart is the peculiar feature of the case, changing suddenly to such a high action, and continuing for two years without alteration in quality or velocity, despite the faithful employment of tonics and heart-sedatives."

FRACTURE OF THE CORONOID PROCESS OF THE ULNA, WITH BACKWARD DISLOCATION OF THE RADIUS AND ULNA.

Dr. W. F. Chappell, of this city, reports the following case: "Mr. S——, aged thirty, while walking on Broadway, slipped and fell backward and to the left, the full weight of his body being received on the palm of the left hand, with the arm fully extended. On rising he experienced great pain in front of the elbow, aggravated by flexion, and relieved by extension. He was seen by a physician within ten minutes of the accident, who pronounced it a severe sprain. At this time all the movements of the elbow were complete. Early next morning he was awakened by the pain. I saw him at 9 A.M., and found the elbow and forearm much swollen and ecchymosed. Olecranon prominent, and the trochlear surface of the humerus resting on the anterior surface of the bones of the forearm. Flexion produced great pain and crepitus over the coronoid process; slight extension relieved the pain and removed the deformity. From the history and symptoms I judged that fracture of the coronoid process and rupture of some of the ligaments occurred at the time of the accident, and dislocation during the night. He remained under my care for three days, when, although fully aware of the risk, he started on a Western trip. After five weeks he returned, with the bones still dislocated and anchylosis complete. With the assistance of Dr. N. G. McMaster I broke down the adhesions, reduced the dislocation, and put the arm in plaster of Paris in the flexed position, and on the eighth day began passive motion. It is now nine months since the accident and the patient is able to flex the forearm sufficiently to place the hand on the back of the head, and all the other movements are natural and complete; but the strength is not equal to that of the other arm when in the extended position."

Progress of Medical Science.

Absence of Vagina.—The Paris correspondent of the *Medical Press* writes that M. Pollaillon observed an interesting case of complete absence of the vagina. A young girl, aged eighteen, suffered great pain in the hypogastric region every month. She never menstruated. On examination, M. Pollaillon found that there was no perforation of the vulva. On the other hand, a hard tumor could be felt through the abdomen. By the rectum something like the os of uterus could be felt. A sound being placed in the bladder and a finger in the rectum, the operator discovered that but a very thin layer of tissue separated the respective walls, and that there was absolutely no vagina. The pain during the ordinary menstruating period became so intolerable that the creation of an artificial vagina was decided upon. To that end a transverse incision was made in the perineum, and pushed on as high as the uterus, separating in its track the walls of the bladder and the rectum. When the incision was sufficiently enlarged, a plug of cotton coated with iodoform was thrust in, and the operation finished for that day. At the end of a few days, seeing that the artificial opening was likely to remain permanent, he decided on perforating the uterus. The os was found after a little trouble, but no opening could be discovered. Accordingly, a small lithotome was passed in, and soon an ounce of black liquid flowed out. Antiseptic washing with sublimate and the placing of five drainage-tubes attached in one bundle in the vagina completed the operation. The girl made a good recovery. The pain ceased entirely, but the courses have not yet reappeared. M. Pollaillon considered that sexual connection was possible.

Some Recent Observations on Acetanilide (Antifebrin).—Since the publication by Cahn and Hepp, calling attention to the value of acetanilide, numerous other contributions to the subject have appeared. From a *résumé* of the more important papers we gather the following (*London Medical Record*, May 16, 1887): All observers agree in considering acetanilide to be a valuable, if not the best, antifebrile agent we possess. Small doses unfailingly reduce the temperature sufficiently without the accompaniment of disturbing symptoms, thus conducing greatly to the patient's comfort. Lastly, and by no means least, the cheapness of this drug is greatly in its favor. Failure of effect is recorded in only one case out of many, viz., a patient of Huber in the Zurich Hospital, with pneumonia. Even 65 grains of acetanilide daily had no effect on the fever in this case, neither had antipyrin. In four other cases the maximum amount given was only 8 grains daily. But to have only five negative results out of two hundred cases is a striking fact. The dose at first should be only 4 grains, so as to learn how the patient tolerates this medicine. Smaller doses than this, even if repeated hourly, have no satisfactory result. The best dose in acute fevers is 8 grains. The remission produced is several degrees, and lasts from four to twelve hours. The lowering of the temperature begins between one and two hours after the dose, and the greatest effect is produced in from three to five hours. The amount given in twenty-four hours is stated in Cahn and Hepp's first publication as half a drachm, but this amount may be greatly exceeded without any danger. Huber gave a drachm, Riese as much as one and one-half drachm. In one case 70 grains were given in twenty-four hours, the only untoward symptom afterward being slight cyanosis. In experiments on animals Cahn and Hepp found that a dose of one ounce at once, or doses of half an ounce daily for a long time, were necessary to produce a toxic effect. In the case of a child with scarlatina, Grüneberg gave nearly 20 grains in the twenty-four hours. As to the collateral effects of acetanilide, increased sweating is the most frequent, though not constant, symptom. Rigors during the succeeding rise of temperature are

more important, but are rarely seen. Huber is in opposition to all the rest in reporting as many as twenty cases of rigors in ninety-five days of observation of thirteen different patients, all suffering from typhoid. The frequency of the pulse is lessened, and its tension increased. On this latter point Fränkel differs from the rest. Collapse was observed twice in the whole series of cases—one perfect collapse after a rather large dose in a patient with phthisis, the other an imperfect collapse in an anæmic typhoid patient after a moderate dose of 8 grains. The urine is increased under its use. Lepine is mistaken in saying there is diminution. Vomiting only occurred twice, and in these two cases the remedy was then introduced *per rectum* successfully. The appetite appears to improve under its use. Whether an acetanilide exanthem exists or not is doubtful. It is at any rate extremely rare. Cahn and Hepp only mention miliaria cysts and rubra. More or less deafness and mydriasis occurred once (Heinzelmann), along with the cyanosis of the face which is mentioned by all the observers, who disclaim, nevertheless, any significance in this phenomenon. Given in acute rheumatism, Riese, Eisenhart, and Cahn and Hepp found it to act almost specifically; but Fränkel found it of no effect, "except once." Lepine (*Lyon Medical*) praises it as a "nervine." The neuralgic pains of subjects with tabes were removed "as if by enchantment" half an hour after one or two 8-grain doses. The same author also found it useful in neuralgia. According to some authors, the drug cut short attacks of intermittent fever.

Ablation of the Uterus after Inversion.—At the Société de Chirurgie, M. Lefort read a paper on ablation of the uterus by ligature after inversion, and insisted on the benignity of the operation. It was the case of a woman, aged thirty-five, who was delivered a year ago with a little difficulty, as the forceps were required. After the removal of the afterbirth, it was found that the womb was inverted. Immediate reduction was attempted, but the inversion returned. Another attempt was followed by a similar result, so that, at the end of a few days, the uterus remained impacted in the vagina, and menorrhagia was present almost constantly. Four months subsequently the woman was examined by M. Lefort, who found a large rounded tumor blocking up the vagina. Reduction was tried under chloroform, but without success, and as the hemorrhage became compromising, he determined to throw an elastic ligature around the pedicle, which was done easily, and in ten days the uterus became detached. The woman made a rapid recovery.—*Medical Press.*

Renal Sarcoma in Infancy.—Dr. Angel Money recently made a communication on the subject of renal sarcoma in infancy, and specially discussed the question whether surgery was justifiable. He related four cases that he had observed at the Hospital for Sick Children. Hæmaturia was not observed in any. All the cases were females, and the ages ranged between eighteen months and thirty-four months. The other kidney was unaffected in each case. One tumor probably began in tissues not strictly renal. One was evidently of suprarenal origin, and this case had enlargement of the external genitals, on which an enormous growth of hair had taken place during the last nine months of the life of a female child aged twenty-one months at death. All the tumors were large and abutted against the diaphragm. There were secondary deposits in three cases, and in the fourth the meso-colon was infiltrated as well as the retro-peritoneal glands. The course of the case was always longer the older the child. A study of recorded cases in which nephrectomy had been performed seemed to show that life was not prolonged even in the successful cases, and the statistics proved the danger that attended the operation. Doubtless if the tumor was detected when small, a chance for surgery existed, but, as a rule, the tumor was not discovered till it had reached a great size, and secondary growths were almost inevitable; so that, in his work on the "Treatment of Disease in Children," he summed up the present situation by saying that removal of the tumor was useless.—*British Medical Journal.*

The Treatment of Colds.—Dr. Whelan states that it is recognized generally that catarrhs are excited *de novo* by exposure to wet, colds, and draughts (*London Medical Record*). Most frequently they develop in delicate and in highly neurotic individuals. When once a catarrh is properly established, the affected person's breath is infectious, in the acute stage of the disease at least. The question arises, What is the nature of the affection? 1. Is it a specific poison comparable to that of the infectious fevers? 2. Does the affection start as an idiopathic inflammation and develop a specific poison which is given off by the breath? 3. Is it of nervous reflex origin purely? An epidemic of influenza would be explained by supposing that within large tracts of country all catarrhal micrococci became suddenly virulent, owing to some climatic or telluric fostering cause, or to some law of heredity or evolution of the organisms themselves. The usual coddling treatment of colds in an ordinarily healthy person should be strongly condemned; there is a deal of wisdom in the saying, "Starve a fever, feed a cold." A person with catarrh should take an abundance of light, nutritious food and some light wine, but should avoid spirits and tobacco. In the very old or very young, or in cases where the general health is not good, due care must be taken, and, above all things, depressants should be avoided. The author recommends as a specific, both as a prophylactic and therapeutic remedy, the following prescription: ℞. Quin. sulphatis, gr. xviij.; liquor arsenical., ♏ xij.; liq. atropinæ, ♏ j.; extract. gentian., gr. xx.; pulv. gum acac., q.s. to make twelve pills. One of these pills should be taken every three, four, or six hours, according to circumstances. If these pills are commenced in the early stage of a common cold, when the affection is confined to the nose and pharynx, the affection will be nipped in the bud. At first one pill should be taken every three or four hours; later on, every six hours. The author's experience goes to prove that a cold seldom lasts three days under this treatment, and believes that the remedy acts as a powerful nervine and general tonic, bracing the patient's tissues to resist the multiplication of the organisms which cause the affection.

The Operative Treatment of Empyema of the Antrum of Highmore.—According to Mikulicz, the indications to be fulfilled in the treatment of this condition are clear and simple (*Archiv für klin. Chirur.*). In every case it should be the surgeon's endeavor to make an artificial opening into the cavity, and to maintain this opening until suppuration has been completely arrested. The methods which establish an opening into the antrum by the mouth have two advantages. The cavity is thus perforated at a convenient and accessible spot. The surgeon can readily apply his instruments, and the after-treatment can be conducted under the control of both his eyes and fingers. Moreover, the perforation is well situated for the flow of pus, and corresponds to the most dependent part of the antrum. There are, however, certain disadvantages attending the operation by the mouth. Suppuration in the antrum often persists for a long time, it may be for months or even years, and it is necessary to maintain the opening until the discharge has closed. This is not an easy matter, as there is always a tendency for the opening to contract and close unless a stiff drainage-tube be worn. Free communication between the antrum and the mouth is attended with inconvenience, and portions of food and other foreign material may pass through the opening into the cavity, decompose there, and set up fresh suppuration. In consequence of these objections to the oral operation, attempts have been made to open up the antrum in another direction. An objection might be made, it is pointed out, to the old operation on physio-

logical grounds. The antrum has no normal connection with the mouth, but is to be regarded as a pneumatic appendage of the nasal cavity, with which, in a healthy condition, it has free communication. If this communication be shut off in consequence of any pathological process, that operation would seem to be the most rational that serves to re-establish the normal condition. The author is opposed to any method of attempting to reach the antrum through the middle meatus. It would, he states, be found very difficult in such attempt to open up the antrum and afterward to inject this cavity. Besides, the perforating instrument would be brought into dangerous proximity to the orbit, which cavity is separated from the nose by only a thin plate of bone. Again, an opening in the middle meatus would be most unfavorably situated for the discharge of a large accumulation of pus. The author advocates an opening made from the inferior meatus. The osseous septum between this portion of the nasal cavity and the antrum is very thick and dense near the hard palate, but soon becomes reduced to the thickness of paper, and may be readily perforated by a stout cutting-instrument. For this purpose a short double-edged knife, or rather cutting-stylet, set on a curved shank, has been devised. This is introduced along the inferior meatus until it reaches the inferior turbinated bone, when its point is turned outward and thrust through the septum into the antrum. The opening having been enlarged by to-and-fro movements of the instrument, the elongated and curved nozzle of a specially devised elastic bell-syringe is introduced, and the cavity of the antrum is washed out. This operation, which proved successful in two cases, is not likely to be attended with any difficulty except in cases of abnormal narrowness of the inferior nasal meatus, of extreme hypertrophy of the inferior turbinated bone, or much thickening of the osseous septum between the antrum and the inferior part of the nasal cavity.

Cæsarean Section.—In the *Edinburgh Medical Journal* Dr. Stuart Nairne contributes a paper on the subject of Cæsarean section as a substitute for craniotomy or other child-destroying operations. The author states that ten years ago he performed craniotomy for the first time, and, on reflecting upon the case, he determined on another occasion to perform Cæsarean section rather than subject the mother to the dangers which might arise from bringing away a child in the form of a mangled mass of bones and brains. Soon afterward he was called to a little deformed creature who was in labor, and Cæsarean section was strongly urged, but two medical men who were present determined to deliver with forceps. After great difficulty a very small child, unrecognizable as such about the head, was drawn out: in a few days the mother died. In a third case, where the author advised Cæsarean section, a mauled dead child was eventually born by the aid of forceps, and the mother made a very tedious recovery. This case made Mr. Nairne decide definitely never to destroy a child *in utero* by bringing pressure on the head or body, so that life must be extinct when delivery was accomplished. The following case came under his care, and his determination to perform Cæsarean section was fulfilled: A lady, aged forty, was pregnant for the tenth time. All the previous children had been delivered between the sixth and seventh months, and none lived. When the author saw her she had completed her seventh month; the child lay transversely in the womb and was living. The woman was very anxious to have a living child. Mr. Nairne told her and her husband that he would not perform craniotomy, but advised Cæsarean section. The woman followed this advice, and as soon as labor was commenced Mr. Nairne was sent for. At 3 A.M., January 20th, the operation was commenced, the patient lying on her back, under the influence of chloroform. An incision being made through the abdominal walls, the uterus came into view; no one part seemed more livid than another to suggest the situation of the placenta, so a small incision was made in the middle line and a finger was introduced into the uterus. The incision was then prolonged upward and downward. A little water escaped, and the right shoulder appeared. By dipping his fingers round the chest of the child, and by a movement of rotation, the author delivered a living child almost instantly. The womb contracted in a measure, the wound in its anterior part gaping widely, leaving the whole interior surface of the left upper part covered with the placenta; this was then separated, but the womb remained soft and bleeding. A hypodermic injection of ergotin was given, causing contraction almost immediately. The uterine incision was then carefully stitched up by eight or nine interrupted sutures, and a bougie passed through the wound down through the os; a tube was also introduced from the vagina into the os. The peritoneal cavity was carefully sponged out, the abdominal wound stitched and closed, and the patient put in bed with a good pulse. Everything went on well until the third day, when urgent symptoms set in, and death took place suddenly on the fourth day. The author remarks that this case shows the necessity for careful research and inquiry into the management of every step of this operation, as he is convinced that a death occurring so long after an operation must be due to preventable causes. No post-mortem was obtained, but there was no doubt about peritonitis being the cause of death.

Hysterical Angina Pectoris.—Allied to genuine angina, due to cardiac ischæmia, are quite a number of pseudo-anginal complaints, attributable, some to gastric dyspepsia, others to a well-marked nervous disorganization. The latter class furnished M. le Clerc with a subject for his thesis. The first case of the kind was recorded in 1812 by Millot, but many more have since been observed by Bertrand, Balfour, and others. The affection in this form is met with principally, but not exclusively, in women, generally before middle age. It occurs more rarely at the menopause and in children. The attacks are longer, more frequent, and more severe than in angina of organic origin. They are remarkable by their onset, which is sometimes central, sometimes peripheral. The differential diagnosis is based on the nature and the seat of the pain, and the presence of some sort of aura, by the multiplicity and variability of the irradiations, which are more eccentric and present a greater range. The attacks are often more or less periodical; they occur oftener by night than by day, and are provoked by psychical impressions (emotion, dreams, etc.), seldom or never by a physical effort of any kind. Their termination is marked by phenomena characteristically hysterical in their nature. The past history of the patient is necessarily of importance. The prognosis is favorable, both as regards a fatal termination and as regards a cure.—*London Medical Record.*

Cinchonidin.—Dr. Legenis has made extended observations on the action of cinchonidin and its salts on the various forms of intermittent fever. His conclusions may be briefly summarized as follows: (1) The salts of cinchonidin are as efficacious as those of quinine; (2) they may be employed in all cases in which the latter are generally used; (3) the sulphate of cinchonidin is well tolerated by the stomach in nervous persons or in those intolerant of quinine, and it does not produce either ringing in the ears, nervous agitation, or tremors; (4) they cost about half the price of quinine and its salts.—*Archives Génér. de Méd.*

Gaseous Enemata in the Last Century.—The rectal injection of "fixed air" was recommended long ago by Priestley as of great utility in "putrid diseases," and Percival in 1768, and McBride in 1776, reported marvellous results from this method in pulmonary phthisis.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 13, 1887.

SUBCUTANEOUS INJECTIONS OF ANTIPYRIN.

THE results of clinical experience have demonstrated conclusively the analgesic action of antipyrin, and have opened up a much wider field of usefulness for this drug than its antipyretic properties could ever have won for it. It would, indeed, not be surprising if a more extended trial in this direction should succeed in establishing as a fact the belief now held by many, that in antipyrin we have a drug which may be made to answer most of the therapeutical indications of morphine, and which is free from many of the serious drawbacks of the latter.

In some experiments, the results of which were communicated in a paper read before the Academy of Sciences (*La France Médicale*, July 23, 1887), M. Germain Sée has shown that antipyrin can be profitably employed subcutaneously for the relief of pain. The ready solubility of the drug in distilled water renders it peculiarly suitable for this form of administration. The dose employed hypodermatically by the author was eight grains, dissolved in as many minims of distilled water. The injections caused at first a somewhat painful sensation of tension, but this rapidly passed away and was speedily followed by marked relief of the painful symptoms. Among the affections for which this method was used were acute rheumatism and gout, neuralgias, angina pectoris, and asthmatic paroxysms.

Two other conditions in which antipyrin was employed subcutaneously with marked success were hepatic and nephritic colic. Among the inconveniences of morphine in the former affection is that it tends to arrest the biliary and intestinal secretions, and thus to retard the cure, or even to provoke a return of the pain. In nephritic colic opium diminishes the renal secretion and, in so far, is contra-indicated. Antipyrin, M. Sée insists, is entirely free from these objectionable features, while it is equally as potent, in suitable doses, to relieve the paroxysms of pain.

There can be no question that, could antipyrin, in subcutaneous injection, be substituted for opium or its alkaloids, it ought to be, especially in those chronic cases in which the danger of provoking the opium habit is by no means slight. But we are as yet comparatively ignorant of the action of antipyrin. We know that it is not a drug that can be given in every case with impunity, for many instances are on record in which it was found to give rise to alarming symptoms. Opium we know very thoroughly—we know its dangers as well as the good results which can be obtained from its judicious use. And until we are equally well acquainted with antipyrin, it would be the part of wisdom and prudence not to prescribe it haphazard and in every case indiscriminately, whenever pain is a prominent symptom.

HYPNOTISM AND CHILDBIRTH.

A VERY interesting communication was presented to the Paris Academy, at its session of July 12th, by M. Mesnet, concerning a case of labor which progressed to a successful termination while the woman was in a state of induced somnambulism. The patient had previously been under Dr. Mesnet's care, and was known to be a good "subject." She was of a neurotic temperament, and had presented many hysterical symptoms of an aggravated character which had been much benefited by treatment.

Labor began normally, but, possibly on account of the exalted nervous susceptibilities of the woman, the pains were more than usually severe, the patient complaining bitterly. Somnambulism was now induced by M. Léon, the interne, but the woman still felt the pains as before. She was then told that her pains were less severe, that they were gradually disappearing, and that she would suffer no more during the rest of her labor. After this she ceased to complain, and declared that she felt no pain, although the uterus was contracting energetically at intervals of two or three minutes. All went well for two or three hours, until the bag of waters burst, when the sensation of pain apparently returned, and the woman seemed to suffer as much as if she had been in the possession of her normal faculties. At the expiration of two hours more the labor was terminated, the woman still being in the hypnotic state. She inquired the sex of the child and expressed keen disappointment on learning that it was not a girl, as she had hoped that it would be.

After the bed had been changed the woman was awakened, and then remarked on the presence of the doctor at such an unusually early hour, and asked if she had slept long. Soon after, having by chance placed her hand on her abdomen, her surprise at the disappearance of the swelling was extreme. She remembered nothing of all that occurred while she was in the hypnotic state. She inquired again as to the sex of the child, and expressed her disappointment as before on hearing that it was a boy. A few hours later she was again hypnotized, and then related all the circumstances attending her confinement during the previous night.

It is, of course, improbable that the analgesic influence of hypnotism will ever be used, except in very occasional instances, in ordinary labor, and the case just cited possesses more interest to the psychologist than to the obstetrician. It is interesting, however, in the highest degree to the metaphysician, since it demonstrates so clearly the possibility of a dual existence. The memory of the woman while in her normal condition was a blank as far as concerned the knowledge acquired by her in the hypnotic state; yet, upon passing again into this condition, she was able to recall perfectly everything that had occurred previously in her somnambulistic existence. It would appear, however, that the converse of this did not apply, for the woman remembered, while hypnotized, much, if not all, that had happened to her in her normal state.

THE DANGERS OF ETHER.

The death of a man, while undergoing an operation for hemorrhoids under ether narcosis, which was recently reported widely in the daily press, serves to emphasize again the fact, which so many are wont to forget or ignore, that ether is by no means a harmless drug. It is true, the reported deaths from ether, when compared with the number of times that the anæsthetic is administered, are very few. Yet they do occur, and they occur with much greater frequency than one who depended upon published cases alone for his statistics would ever imagine. In the interesting discussion on the relative merits of ether and chloroform, which took place at a meeting of the Academy of Medicine in April last, many instructive facts were presented which are worthy of the most careful consideration. We do not propose to review that discussion here (those who are sufficiently interested in the subject will find a full report of the meeting in The Medical Record of April 23, 1887), but there is one point which we feel cannot be too strongly insisted upon. That is the utterly reckless manner with which ether is administered, as though it were so much pure air, of which too much could not by any possibility be taken into the lungs.

The administration of ether in our hospitals, with few exceptions, is entrusted to the junior assistant, who is usually fresh from the school, well grounded no doubt in theoretical knowledge, but necessarily without practical experience. He has been taught by his instructors and his text-books that chloroform is a very dangerous drug, while ether is comparatively harmless. He has not learned to appreciate the vital significance of the adverb in this sentence, and he leaves the college with the impression strong in his mind that ether is an absolutely safe anæsthetic, and he uses it accordingly. The administration of the anæsthetic is often conducted in a separate room; the senior assistants are in the operating-room, putting things in order for the operation; and the junior has the poor patient all to himself. If he is an observant man and interested in all that pertains to his calling, as he generally is, he soon learns passably well how to administer the ether; but he is a fortunate man if he does not learn also, from disagreeable experience, that ether is not as innocent a fluid as he supposed. But in the meanwhile the patients' lives are in danger.

This is no fancy sketch, but is what actually occurs in nearly every hospital in the country once or twice every year. And the apothecaries' accounts will generally show that the amount of ether consumed is much greater, in proportion to the number of operations performed, immediately after a change in the hospital staff than it is a month or two later. This increase represents the excess of ether inhaled by the patients over what was necessary to produce anæsthesia.

But recklessness in the administration of ether is unfortunately not confined to junior internes, whose sin is one of ignorance, and more than one life has been sacrificed to the contempt for ether, in the mind of the practitioner, which is bred of familiarity. The administration of ether should be conducted with as much caution as is that of chloroform, for though undoubtedly safer than the latter in most cases, it is yet a dangerous drug, and one that demands constant, intelligent, and watchful care on the part of the administrator, who should never for an instant forget the responsibility that rests upon him.

SALOL, SALINAPHTHOL, AND THE DIAGNOSIS OF "MOTOR" DYSPEPSIA.

Salol is a compound body formed of salicylic acid and phenol, which is decomposed into its constituents in the intestine. Professor Lépine (*The Lancet*) advocates the substitution for it of a new compound, obtained by M. Merck, and which has been called naphthol-salol, naphthalol, etc., and for which he proposes the name salinaphthol:

$$C_6H_4.OH.CO_2H + C_{10}H_7.OH = C_6H_4.OH.CO.OC_{10}H_7 + H_2O.$$

Salicylic acid + β-naphthol = salinaphthol + H_2O.

The efficacy of the new drug depends upon its decomposition in the intestine by the pancreatic secretion, and it is therefore inert and unirritating in the stomach. The advantage claimed for it over salol is that when split up into its component parts there remains besides the salicylic acid, which is the therapeutic agent, a by-product, β-naphthol, which is less toxic and less absorbable than the phenol which results from the decomposition of salol.

The objection which may be made to this is that salol and salinaphthol do not surely split up as claimed.

Basing his work, however, on this view, Professor Ewald has lately devised a new method for investigating the motor power of the stomach. "We know," he says (*British Medical Journal*), "pretty well the chemical changes taking place during digestion, but our experiments on the time required by the stomach for transmitting food into the duodenum have hitherto been limited to patients suffering from gastric fistula. Trials made in the normal state of health have always failed. A means has now been found in salol excellently adapted to solve this question. Salol, on reaching the bowels, immediately dissolves, and shows almost instantly in the urine as salicyluric acid. This easily yields a red precipitate with chloride of iron. This reaction will show almost exactly the moment of the entrance of food into the bowel. The urine of seven persons in sound health showed the reaction to take place mostly within three-quarters of an hour, rarely within half an hour. It took two to three hours in seven cases of 'ektasia ventriculi,' this disease being distinguished by loss of motor power in this organ. On applying the electric current to the abdomen, the reaction took place in normal cases a quarter of an hour sooner; in cases of enlargement of the stomach, half an hour sooner. This experiment says much in favor of this method of treatment."

If Professor Ewald's views, based on only fourteen cases, are confirmed, a new and valuable addition to our means of diagnosis has been obtained.

QUACKERY AND MEDICAL LAWS IN GERMANY.

The Dresden Medical Society is leading in a movement to secure the re-enactment of the law against quackery, which for several years has been abolished in Germany. In a debate over the subject before the Berlin Medical Society (*British Medical Journal*), Herr Becher said that quacks had increased in number as well as in authority and dignity. The old law had been abolished

trusting to the common sense of the public. This hope has been disappointed. The Dresden physicians, he added, were not standing alone in making this petition, having been joined already by forty-six medical associations in different parts of Germany—in all 3,000 members. Thirty-four associations more had expressed their sympathy, being prevented from joining in the petition merely by some matters of form. Only nine associations had voted against the petition; these numbers were worthy of consideration. Professor Mendel had maintained that the existing laws were all-sufficient to prevent any great abuse; but Herr Becher was not of that opinion. The quack made an agreement with the patient against which the judge was powerless. If even one of them was caught in the nets of law, all experience showed that they were more leniently treated by the jury than any medical man who happened to have made a mistake. Every barber called himself "assistant-surgeon;" the most outrageous mountebank was marked in the Berlin Directory as "Medical Director." The magistrate of Chemnitz (Saxony) appointed a quack as physician to a public charge, although the law expressly demanded a qualified physician, and the Bundersrath confirmed the appointment. The public required to be enlightened through the law. Herr Becher's motion was carried by 168 votes against 164. The Berlin Medical Association being the most liberal of all, it is most probable that the General Union of German physicians assembling this summer will adopt this petition.

In connection with this movement it would be well for our German brethren to study the results of some of the medical legislation in this country.

The following statistics regarding the working of the registration law in Illinois have recently been published:

	July 1, 1877.	July 1, 1887.
Total number engaged in practice.....	7,400	6,180
Graduates and licentiates.....	3,600	5,704
Non-graduates.....	3,800	476
Percentage of graduates and licentiates.	48.6	92.3
Percentage of non-graduates.....	51.4	7.7

When the law went into effect there were 1,923 physicians in the State who were not qualified, and therefore could not comply with its provisions. Of these by far the greater number left the State, others abandoned practice, while many qualified themselves, and graduated or passed the board.

THE PROPHYLACTIC SIGNIFICANCE OF EPISTAXIS.

In a recent number we referred to the importance, from a diagnostic point of view, of nose-bleed occurring in adults. But the phenomenon is of even greater importance, perhaps, as an element to be considered in estimating the probable outcome of certain affections. We purpose, therefore, to direct our readers' attention briefly to this symptom in its prognostic aspect.

Epistaxis, when in considerable amount and persistent, coming on after a blow or a fall upon the head, is of evil prognostic import, pointing, as it usually does, to fracture of the base of the skull. When occurring at the beginning of an eruptive fever, nose-bleed should cause no alarm; but when it comes on during or after the period of eruption it is of graver import, since it is then usually an indication of malignancy or of a hemorrhagic tendency in the disease. When it occurs frequently in pertussis it is a bad sign, not necessarily portending death, but indicating that convalescence will be slow, by reason, probably, of the anæmia induced by the repeated losses of blood.

In typhoid fever epistaxis occurring at the beginning of the disease is of rather favorable prognostic import—or, at least, it does not forebode evil—but when it appears late in the course of the affection it is a grave sign, indicating profound changes in the blood, and often being only a precursor of dangerous intestinal hemorrhage. In diphtheria nose-bleed is not a favorable symptom, as it is usually an indication that the local disease-process is spreading, and that it has begun to invade the mucous membrane of the nasal cavities.

Repeated attacks of epistaxis in the later stages of Bright's disease are of evil augury. In such cases the hemorrhages may not infrequently be regarded as an evidence that the coats of the arteries have undergone atheromatous changes. In the malarial cachexia, also, the frequent recurrence of nose-bleed is an unfavorable symptom. Epistaxis occurring in the aged suggests the danger of cerebral apoplexy, yet its occurrence in such cases cannot be regarded as an evil, since its effect is undoubtedly to relieve cerebral congestion.

It is said that those who are subject to nose-bleed in childhood are very apt to suffer in later life from rheumatism. And it is also believed by some authorities that such individuals are more liable to hæmoptysis, which seems to follow as a sequel of the epistaxis when the latter has ceased. It is, however, very doubtful whether any relation, other than that of mere coincidence can be traced between the two forms of hemorrhage in such cases.

A New Antipyretic.—Dr. Kobler, of Vienna, has been experimenting with a substance, called acetphenetidin, which is said to be analogous in its action to antifebrin. It is a reddish powder, odorless and tasteless, very slightly soluble in water, but readily soluble in alcohol and glycerine. The temperature in febrile cases falls two or three degrees in the course of about three hours after a dose of eight grains has been administered. The defervescence is said not to be accompanied by cyanosis or sweating, and none of the patients showed any symptoms of collapse. The pulse is diminished in frequency, but its tension is increased.

What Shall We Wear?—The *Epoch* of August 5th contains several short contributions on "How to keep Cool and Well in Summer." Dr. Cyrus Edson says that it "is best to wear dark clothing in the summer. The black absorbs heat when it is in the sun's rays. On the other hand, the heat will pass out through the black textures rapidly, so that the radiation of the heat from the body would be much freer in a person clothed in black than white." On the following page Dr. Willard Parker observes: "The best way to dress is to wear thin woollen material next the skin, as little outside clothing as possible, and that of a light color. Dark colors draw the heat and light ones repel it." This is calculated to confuse the average layman, and he will probably decide to wear the clothes he is now provided with, whatever their color may be.

News of the Week.

The Subscriptions for the International Congress from various State medical societies and individuals, had amounted to about eight thousand dollars on the first of this month.

The International Medical Congress.—The programme for the International Medical Congress, to be held in Washington in September, has been completed, with the exception of a definite arrangement for a reception by President Cleveland. The meeting will be opened on Monday, September 5th, at Albaugh's Opera House, when the Congress will be organized, the report of the secretary-general submitted, and an address of welcome delivered by Secretary Bayard. In the evening a conversazione will be held at the Pension Office. General meetings will be held on each morning of the week, and meetings of special branches of the medical profession will also be held each day of the week, except Saturday. Addresses will be delivered during the session of the Congress by Dr. Austin Flint, of New York, on "Fever, its Causes and Rational Treatment;" by Dr. Mariano Semmola, of Naples, Italy, on "Bacteriology and its Therapeutical Relations;" by Dr. P. G. Unna, of Hamburg, Germany, on "The Relations of Dermatology to General Medicine;" by Dr. G. Fielding Blanford, of London, on "The Treatment of Recent Cases of Insanity in Asylums and in Private Houses;" by Dr. A. Uteaud, of Paris, on "The Influence of Discoveries of American Surgeons on the Development of Gynecology in Europe," and by Dr. Neudorfer, of Vienna, on "The Military Medicine of the Present and that of the Near Future." The social features of the meeting will be a reception by citizens on Wednesday evening, a general reception and buffet banquet at the Pension Office on Thursday evening, and a trip to Mount Vernon Saturday afternoon.

Charges against Health Officer Smith.—Governor Hill, of New York, has, through the Attorney-General, brought a writ of quo-warranto against the Quarantine Commissioners. Proceedings are also being arranged against Health Officer Smith. It is charged that he has made a corrupt agreement by which the profits of his office are divided, and that after he has received a share to pay him for being health officer, the remainder of the receipts are, in pursuance of this agreement, distributed between ex-Senator Thomas C. Platt, ex-Marshal Lew Payn, ex-Governor Cornell, and ex-Lieutenant-Governor Hoskins. The amount alleged to have been divided last year is estimated at $60,000. It is understood that the basis of this charge is the rag disinfection business, concerning which so much has been said of late, and concerning which, from a scientific standpoint at least, so much needs to be explained.

Yellow Fever at Key West, Fla., and Delaware Breakwater.—Nine new cases of fever have been reported by the Board of Health of Key West since August 8th. There have been no deaths. The last one hundred and fifty cases have been nearly all children, with less than two per cent. of mortality. The bark Ada Gray, from Havana, arrived at Delaware Breakwater August 8th, with one case of yellow fever on board.

Another Medical College.—Some weeks ago the Board of Regents of the Oregon State University authorized the formation of a medical college in Portland, as part of the university, and issued a charter therefor. The department has now been organized, a faculty of thirteen members has been elected, and the early appearance of the first annual announcement is anxiously awaited.

A Rival to Christian Science Healing Institutes has made its appearance in St. Louis. It is to be called the Hygienic College of Physicians and Surgeons. The incorporators define disease as an abnormal vital action, which is caused either by an improper use of things normal, or by the presence of things abnormal. The true healing art seeks to regulate the use of the former and to rid the system of the latter. The materia medica embraces such powerful drugs as clothing, temperature, rest, food, sleep, drink, bathing, exercise, air, mechanical appliances, and last, but by no means least in its efficacy, mental and emotional influences. The school proposes, if it is allowed to do so, to confer degrees of doctor of medicine upon its students.

Dr. F. Schultze, of Heidelberg, has been called to the chair of general pathology and therapeutics at the University of Dorpat.

A Death Under Ether.—A case is reported from Philadelphia of death under ether. The patient was undergoing an operation for hemorrhoids, when he was noticed to be breathing irregularly, and despite all that could be done, died without recovering consciousness.

Beri beri in England.—Several cases of beri-beri have recently occurred on the Chinese transport-ship Too Nan, stationed at Newcastle-upon-Tyne. The sailors were from different parts of China, but those from the southern provinces only were attacked. The cases were observed by Drs. Slater and Oliver, who report them in the *Lancet* of July 23, 1887.

Death of a Bone-setter.—Mr. Huttor, who had gained considerable notoriety in England for his skill in "bone-setting," died a short time ago from accidental poisoning.

The Presidency of the International Congress of Hygiene.—Dr. Schneider has resigned the post of President of the International Congress of Hygiene at Vienna. As his successor the Bureau of the Organizing Committee have unanimously elected Professor E. Ludwig.

A New Bacillus of Malaria.—Dr. Schiavuzzi claims to have isolated a bacillus from the air of malarious districts, which, after culture, excited malarial fever when injected into rabbits.

The Cholera is reported to be increasing in Sicily, and to have appeared also in Sardinia.

Deaths of Foreign Medical and Scientific Men.—The following deaths are announced in the *Lancet* of a recent date: Dr. Georg Wiesner, Senior Medical Officer of the Hospital of the Holy Ghost, Frankfort-on-the-Main, and Sanitary Councillor; Dr. Grewingk, Professor of Mineralogy in Dorpat; Dr. Alexander Reumont, Sanitary Privy Councillor of Aix-la-Chapelle, at the age of sixty-nine; Dr. Kempen, Knight of the Order of Leopold, a distinguished Belgian Military Surgeon.

Reviews and Notices of Books.

Surgery of the Kidney. By W. Bruce Clark, Assistant Surgeon, St. Bartholomew's Hospital. 8vo, pp. 176. London: H. K. Lewis. 1886.

This volume treats of the normal anatomy of the kidney, and next in order of the renal deformities which have a surgical importance. Then follows the description of the various lesions amenable to surgical treatment. The pathological memoranda are concise, perhaps in some instances rather superficial. A special chapter is devoted to the consideration of the positive determination of the presence of two kidneys—a matter which bears directly on the possibility of operative measures. The style of the book is most commendable. It is terse and clear. Numerous well-executed plates illustrate the text. A full bibliography is appended. It will afford the reader a full scope of the present status of renal surgery.

Anatomy, Descriptive and Topographical. By Carl Heitzmann, M.D., Vienna. Translated by Louis Heitzmann, M.D. 4to. New York: J. H. Vail & Co. 1887.

This is a work of two parts, having in all over five hundred pages, and over six hundred illustrations. It is a reproduction (though in its second part by no means a literal translation) of "Heitzmann's Anatomischer Atlas," published sixteen years ago. The latter has had in Germany and Austria a sale of over thirty thousand copies, and appears to occupy the sphere filled by the familiar "Gray" in England and America. Too much praise cannot be awarded the author for his excellent plates, particularly those illustrative of sections of the body and limbs made at various levels. The descriptive text is, however, very meagre, and entirely inadequate to meet the wants of a beginner. As a work of reference for an advanced student, or for a teacher of anatomy, it is most excellent. It would be a valuable addition to the library of any surgeon.

Disorders of the Male Sexual Organs. By Samuel W. Gross A.M., M.D., LL.D. Third edition. Revised. 8vo, pp. 168. Philadelphia: Lea Brothers & Co. 1887.

This is undoubtedly one of the very best manuals ever published on male sexual disorders. It has been translated into the Russian language. It is well known that the author regards impotence and spermatorrhœa as due to reflex disturbances of the genito-spinal centre, and not as functional diseases of the testicles. They are due, in his opinion, to lesions of the prostatic urethra. He lays especial stress upon masturbation as a cause of stricture. Every physician is called upon to treat sexual disorders, even though he is a general practitioner. He can find no better collection of clinical facts than in Dr. Gross' work, and no better description of therapeutic measures to be employed.

A Treatise on Diphtheria, Historically and Practically Considered: including Croup, Tracheotomy, and Intubation. By A. Sanné, Docteur en Médecine, Ancien des Hôpitaux de Paris, Membre de la Société Anatomique, etc.; Chevalier de la Légion d'Honneur. Translated, annotated, and the Surgical Anatomy added; illustrated with a full-page Colored Lithograph and many Wood Engravings. By Henry Z. Gill, A.M., M.D., LL.D., late Professor of Operative and Clinical Surgery in the Medical Department of the University of Wooster, at Cleveland, O., etc.

Sanné's "Traite de la Diphthérie" is the largest and one of the fullest of the works on its special subject. It is also one of the most readable, but is not the most concise. Its subject is discussed under so many divisions and subdivisions that, while exhaustiveness of consideration may be thereby promoted, a certain amount of repetition is inevitable. Yet it is none the less true that the work is a storehouse of valuable information which has so long been appreciated and utilized by teachers and writers in this and other countries, that it is surprising that it has had for ten years to await translation into English. In performing this task, and performing it so well, Dr. Gill has rendered to English readers a service which will doubtless be highly appreciated by many.

On the various mooted questions which his subject involves, M. Sanné takes a decided stand. He believes in the identity of membranous croup and diphtheria. He believes, also, that diphtheria is "a disease which is, *totius substantiæ*, primarily general. All its forms, so diverse in appearance, are but different manifestations of a single cause which contaminates the whole economy." On the bacterial question he pronounces that "new observations and solid proofs are needed to establish diphtheria as a parasitic disease."

The translator has prefixed to the work a profusely illustrated chapter on the surgical anatomy of the pretracheal region, with special reference to tracheotomy in children, which operation he pronounces "one of the most unpleasant and dangerous, as met with under the usual circumstances, of all the operations which the surgeon is called upon to perform." The translator also makes some other addenda, among which are a very brief abstract of the bacterial researches of Loeffler, and a too short article on Dr. O'Dwyer's method of intubation. It is difficult to see why a nearly useless eight-page "list of authors referred to" should have been substituted in the translated volume for the valuable marginal references to titles of works in the original.

Hand-book of Materia Medica, Pharmacy, and Therapeutics. By Samuel C. L. Potter, M.A., M.D. Pp. 828. Philadelphia: P. Blakiston, Son & Co. 1887.

This book contains a great variety of useful information. Aside from the Materia Medica, it tells how to write prescriptions, how to give antidotes for poisoning, and how to prescribe for diseases, somewhat after the manner of the "Family Physician" book. It will commend itself to the young physician, because of the minute and practical directions which are here given, and which are wanting in more pretentious works.

Clinical Manual for the Study of Medical Cases. Edited by James Finlayson, M.D. Pp. 683. Philadelphia: Lea Brothers & Co. 1886.

This "Manual" is one of the most complete and perfect of its kind. It goes thoroughly into the question of diagnosis from every possible point, and if diagnosis were not a matter of mature experience and constant practice outside of text-books, this guide to the study of medical cases would be very useful. As it is, it must lead to a thoroughness of observation, an examination in detail of every scientific appliance, and a study of means to the end which cannot fail in laying an excellent foundation for the student for future success as an able diagnostician.

Foods and Food Adulterants. Bulletin No. 13, U. S. Department of Agriculture. Part First: Dairy Products. 1887.

Dr. Wiley, the department chemist, has collected a number of facts regarding butter, milk, and cheese, and their adulterants, and has added some work of his own. The Bulletin is not a scientific document of a high order, but contains considerable interesting information.

Nervous Diseases and their Diagnosis. By H. C. Wood, M.D., LL.D. Published by J. B. Lippincott Company. 1887.

The writer offers an apology for adding to the large list of treatises upon nervous diseases which have already

been published, but he does so because of his long experience and at the earnest solicitation of some of his former pupils, "who insisted that the method of teaching which had been gradually evolved in the weekly clinics of the University Hospital was different from that commonly in vogue, and if followed out would give freshness to an old subject." This method is shown to be a grouping of diseases according to their symptoms, such as paralyses, motor excitements, etc., rather than upon an anatomical division. This, indeed, gives the work a special value, and perhaps its only value, which probably students will appreciate rather than neurologists, to whom the book will not present anything decidedly new. The work is devoted entirely to "diagnostic neurology," a title which heads each leaf. There is a wide-spread belief among those who do not make a specialty of nervous diseases that diagnosis constitutes by far the greater part of a neurologist's task, and that this done, there remains almost no field for successful treatment, in regard to which they have a hopeless despair.

When, therefore, Dr. Wood's twenty-five years' experience blossoms only in diagnosis, and not in the advocacy of successful measures to combat the so often terrible nervous diseases, this book goes to confirm this despondent opinion. Possibly Dr. Wood has in mind to publish in the future a work on the treatment of nervous diseases, which, with his wide opportunities for observation, coupled with his therapeutical knowledge, could hardly fail to be of value not only to students but to the profession at large.

Drug Eruptions. A Clinical Study of the Irritant Effects of Drugs upon the Skin. By Prince A. Morrow, A.M., M.D., Clinical Professor of Venereal Diseases University Medical College, New York. 8vo, pp. 199. New York: William Wood & Co. 1887.

As the author states in his preface, "the abnormal phases of drug action are comparatively an unexplored field." He has collected in this volume our authentic knowledge upon the subject. First come pages on history, definition, classification, general characteristics, etiology, pathogenesis, diagnosis and treatment of drug eruptions. Then follow the clinical memoranda concerning the individual drugs themselves. The alphabetical arrangement of the latter makes reference easy. The drug list is very complete, and includes some of the more modern remedies, as antipyrine. A well-executed colored plate illustrates the skin lesions of iodide of potassium. An exhaustive bibliography is appended. We cannot but congratulate the author on the great service he has done the profession in compiling this volume.

French Neurological Journals. — Neurology in France is well represented by the bi-monthly journal, *L'Encephale*, edited by Ball and Luys, and by the quarterly *Archives de Neurologie*, edited by MM. Charcot and Bourneville.

The National Dispensatory, containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicines, etc., by Alfred Stillé, M.D., LL.D., and John M. Marsh, Phar.D. Fourth edition. Pp. 1781. Philadelphia: Henry C. Lea's Son & Co. 1886.

The fourth edition of this well-known work appears with many additions, and bears evidence of careful revision throughout. It has been the aim of the authors to include a notice of all the new remedies which have won for themselves suitable recognition among reliable therapeutical agents. Among those which are more or less exhaustively treated may be mentioned Antipyrine, Cocaine, Hydrochlorate, Cascara Sagrada Fabiana, Franciscea, Gymnocladus, Hypnone, Iodol, Lanolin, Menthol, Thalline, and Urethane. The work is thoroughly up to the times, and will maintain its reputation as an authority on the subjects of which it treats.

Handbook of Treatment. By J. Milner Fothergill, M.D. Third American, from the Third English Edition. 8vo, pp. 660. Philadelphia: Lea Brothers & Co. 1887.

The ground covered by this well-known treatise is that of "an attempt of original character to explain the *rationale* of our therapeutic measures." No one who has read it has failed to be impressed with its plain common-sense and valuable suggestions, born of a wide professional experience. It is a book which has a wider sale in America even than in England. The present edition covers substantially the same ground as the former ones, except for revisions and the addition of two most interesting and valuable chapters, viz., "The Dietary in Acute Disease and Malassimilation," and "The Management of Convalescence." The motto of the latter is "Festina lente." In regard to the former, probably no practitioner of modern times understands the science of dietetics better than Dr. Fothergill. Every physician should own a copy, read it carefully, and then —read it again.

A Manual of Weights and Measures, including Principles of Metrology; the Weights and Measures now in Use; Weight and Volume, and their Reciprocal Relations; Weighing and Measuring; Balances (Scales) and Weights; Measures of Capacity; Specific Weight and Specific Volume, etc. With Rules and Tables. By Oscar Oldberg, Pharm.D., Professor of Pharmacy and Director of the Pharmaceutical Laboratory in the Illinois College of Pharmacy; the Department of Pharmacy of the Northwestern University. Second edition, revised. Chicago: Chas. J. Johnson. 1887.

This is a book of great value to all physicians at the present day, when every scientific work published abroad, and many of those appearing in this country, make use of the metric system of weights and measures. Very few physicians who learned the old system at the commencement of their studies are able to comprehend at first glance the metric system, but are usually obliged to go through a more or less laborious calculation before they are able to translate the figures which they meet with in their reading. This little work not only explains the differences between the two systems and gives simple rules for the conversion of one into the other, but has numerous tables by means of which the equivalents can be read off at a glance, thus saving much time and mental effort.

The author possesses the happy faculty—which is so necessary for a teacher or a writer—of presenting his facts in a form in which they are readily intelligible to the reader. We would recommend all who are yet unfamiliar with the decimal nomenclature to read this book, and to have it by them, where it may be readily referred to in case of need.

Congenital Club-foot; its Nature and Treatment. With Especial Reference to the Subcutaneous Division of the Tarsal Ligaments. By Robert William Parker, Surgeon to the East London Hospital for Children, and to the Grosvenor Hospital for Women and Children. London: H. K. Lewis. 1887.

In this book Mr. Parker gives us a very clear description of club-foot, its causes, pathology, and mode of treatment. He regards the deformity as due, in the majority of cases, to mechanical causes acting during intra-uterine life, or, in other words, that what is a deformity after birth is a physiological condition during fœtal life. This is practically the same theory that was advanced by Dr. Berg, of this city, several years ago. In the treatment of club-foot, the author regards the subcutaneous division of the tarsal ligaments as an essential feature in the great majority of cases, as it is upon their contraction, he believes, that the persistence of the deformity de-

pends. Mr. Parker states his case very clearly, and adduces strong arguments in support of his views. The work must be considered a valuable addition to the literature of orthopædic surgery.

Ratgeber für Mütter. Eine ergänzung zu Dr. H. Dümlings "Bau, Leben und Pflege des menschlichen Körpers." Von Dr. C. Sihler, praktischem Arzt in Cleveland, O. St. Louis: Louis Lange Publishing Company. 1884.

This little book is a sort of appendix to the work of Dr. Dümling recently noticed in these columns, and contains good advice to mothers during pregnancy and the lying-in period.

L'amputation du Membre Supérieur dans la Contiguite du Tronc (Amputation Interscapulo-Thoracique). Par Paul Berger, Chirurgien de l'hôpital Tenon; Professeur agrégé à la Faculté de Médecine; Membre de la Société de Chirurgie. Avec figures dans le texte, et 2 planches en chromolithographie. Interscapulo-thoracic Amputation of the Arm. By Paul Berger. Paris: G. Masson. 1887.

In this treatise of nearly four hundred pages the author discusses at great length the subject of amputation of the upper extremity with removal of the scapula. The histories of fifty-one cases are given, and the questions of the indications and the method of performing the operation are discussed most completely.

Controlling Sex in Generation. The Physical Law Influencing Sex in the Embryo of Man and Brute. By Samuel Hough Terry. 12mo, pp. 209. New York: Fowler & Wells Co. 1887.

About one year ago, the first edition of this book appeared. It received an extended editorial comment from The Medical Record. This article was widely quoted, and for several weeks there was quite an elaborate discussion upon the topic. The present edition of Mr. Terry's book is the second and contains "an appendix of corroborative proofs." A supplementary chapter contains answers to objectors. The theory put forth is that the sex of the embryo, resulting from a given conception, is the opposite of that of the party having the higher stage of sexual excitement at the time such conception occurred.

This theory is now fairly well established in the scientific world. In the appendix, the experiences of several well-known breeders of blooded cattle bear direct testimony to the truth of this view.

On page 134 occurs this paragraph: "There seems to be good reason for concluding that this mysterious influence, which brings together the two sexes in reproduction, is one of the phenomena of electricity," known in some of its phases 'as animal electricity,' and that it is governed by the somewhat mysterious laws of that fluid." The male is regarded as being positive, and the female negative. Dr. Franz Simon has found that the menstrual fluid is acid, while semen is alkaline. By the phenomena of "induction" and "residual discharge," there "must always be in the male parent an influence tending to induce the negative or female form in the germ he produces." In the female, the opposite prevails. But either party may be so feeble in the sexual desire that the residuary discharge may remain either decidedly positive or negative, that is, either a male or female embryo may result.

Many have objected to this latter aspect of Mr. Terry's theorem, that actual fecundation does not take place till two or three days after insemination. Hence, as there is not actual conception at the moment of contact between the male and female elements, the electric theory cannot hold. Mr. Terry makes a double rejoinder to these objectors.

First. "That admitting this delay, whatever vigor was imparted to the two, male and female, products at insemination would proportionally inhere at their junction with the same result as if their junction had been immediate."

Second. "I . . . claim that there must at once, on insemination, be a connection established between the male and female products. Just what this connection is, with our present knowledge it is not possible to say." An argument is found in the superfœtation of dogs, where the bitch is coupled to two different dogs in the same period of heat, and the subsequent litter shows puppies strongly resembling each father.

The foregoing are but a few of the many interesting facts and views advanced by this most intelligent layman, to whom the profession should feel under deep obligation. His volume is a most readable one.

Report of the Surgeon-General of the Navy (Dr. F. M. Gunnell) for 1886. 8vo, pp. 126. Washington: Government Printing Office.

Government reports are not generally considered interesting reading, but an exception must be taken to this one, which contains much valuable information, including communications from the various naval medical officers on foreign stations, and a full report upon our various naval hospitals. Concerning the medical corps the Surgeon-General speaks as follows: "I have to invite your attention to the condition of the medical corps of the navy. Its vacancies have not been filled for several years, resignations, deaths, and retirements having depleted it more rapidly than candidates have been obtained. The Bureau has not been willing to lower the standard of requirements, and it is impossible, with the present inducements offered, to find young medical men possessing the necessary qualifications, who are disposed to become medical officers of the navy."

The Year Book of Treatment for 1886. 8vo, pp. 304. Philadelphia: Lea Brothers & Co. 1887.

The contributors to this volume are all English physicians, who have summarized the important facts from medical literature in all languages. The book gives a very fair idea of the year's progress. Most of the extracts are made without comment. Interspersed among the pages are valuable bibliographical memoranda.

Phthisis in the United States.—Contrary to the opinion generally entertained, this country, taken as a whole, would seem to be favored above others as regards the liability of its inhabitants to pulmonary phthisis. According to Hirsch, the average number of deaths from phthisis is about three per thousand, and in many of the more populous regions of Europe it runs up to six or seven per thousand. In a paper on the "Geographical Pathology of Consumption," read by Dr. G. W. McCaskey before the Indiana State Medical Society in May, 1885, a number of statistics gathered from the United States Census Reports are presented, showing the mortality rate from the disease in this country. These tables reveal the fact that the mortality from phthisis in the whole country is only 1.8 per thousand, or less than that in Switzerland. Of course, the large centres of population present a much less favorable showing than this. The New England and Middle States and California show the highest percentage of deaths, the Interior and Lake States are very near the average for the whole country, while the South Atlantic and Gulf States, and the States and Territories west of the eighty-fifth meridian (except Texas and California) have a mortality of hardly more than one per thousand. Another fact at variance with the general belief, which is shown from Dr. McCaskey's tables, is that consumption is not, with anything like uniformity, more prevalent on the sea-coast than inland.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 13, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. G. C. Freeborn presented, in behalf of a candidate, a specimen of *carcinoma of the uterus.*

Dr. Wackerhagen presented

THE UTERUS AND ITS APPENDAGES EXTIRPATED PER VAGINAM FOR CARCINOMA.

Mrs. H——, thirty-five years of age, a native of the United States, a housewife, and the mother of two children, came under his observation in consultation with Dr. J. E. Gregory, of Brooklyn, March 26, 1887. She had been suffering from pains and hemorrhage, with offensive and irritating discharge, since last December. Her general health had become considerably impaired from loss of sleep and appetite, and she was anxious to take the risk of an operation for the extirpation of her diseased uterus.

The patient was anæsthetized with ether, and, after thorough irrigation of the vagina and uterus with sublimate solution 1 to 1,000, the uterus was drawn down well with vulsellum forceps in each cervical lip. Two stout silk ligatures were then passed, by means of metallic spindles, through the left and right vault of the vaginal wall, for the purpose of including the uterine artery. An opening into Douglas' cul-de-sac, which was made with scissors (blunt), permitted the introduction of a finger into the peritoneal cavity, for the proper placing of the succeeding ligatures, but before these were applied the general peritoneal cavity was protected by an antiseptic sponge, and the mucous membrane and peritoneum covering the distal portion of the stump were sewn together by a continuous catgut suture, this last manœuvre effectually controlling hemorrhage. With a sound introduced into the bladder, a similar opening was made anteriorly. Here, also, the peritoneum was everted by a tenaculum and united to the vaginal wall by a continuous suture.

The left index-finger being now carried across and behind the left lateral mass between the two openings penetrating the peritoneum, this tissue was tied off in five sections. Attempting to carry out the same plan on the right side, it was found that the anterior incision had been too short and the finger could not pass so large a mass, to guide the ligating of this right vaginal wall, and consequently the ligation was made from both extremities toward a common point. This accomplished, the whole vaginal vault had been securely ligated and separated from its uterine attachments, and hemorrhage stopped without the loss of more than an ounce of blood.

The fundus uteri was now turned out and the ovaries brought down. There remained attached a portion of both broad ligaments on each side. These were tied off with silk, cut, and the uterus and its appendages laid aside. A portion of one broad ligament, and a small mass of the posterior stump oozed a little blood and demanded a secondary ligation. The stump was then stitched to the vaginal wall in several places to prevent its retracting and becoming inaccessible in the event of secondary hemorrhage. After thorough cleansing internally and externally and removing the sponges, which had very effectually shielded the peritoneal cavity (for their innermost surfaces were scarcely discolored), iodoform dressings were applied and the patient placed in bed. Her pulse was remarkably quiet and natural, and consciousness was restored within a short time. No vomiting occurred, and up to the present writing the temperature had not been above 99⅖° F. Dr. Wackerhagen was under obligations to Dr. Paul F. Mundé, who kindly assisted him in the operation.

The specimen was a multiparous hyperplastic uterus, cut longitudinally through the posterior wall, and with a tributary cut extending into the right cornua. The body was four inches long, with walls showing an excess of fibrous elements. The major portion of the enlargement was in the cervix, and of this particularly the right half of the anterior lip. By reason of this asymmetry the os externum did not form the apex of the irregular excavation in the invaginated portion, but was fully seven-eighths of an inch lower and five-eighths of an inch farther to the left. The mucous membrane was hyperæmic and thickened. The right ovary was cystic.

The Society then went into executive session.

Stated Meeting, May 25, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. Joseph W. Howe presented a patient on whom he had

LIGATED THE FEMORAL ARTERY UNDER COCAINE—SECONDARY HEMORRHAGE—TRANSFUSION OF LITTLE'S SOLUTION—RECOVERY.

The history of the case was as follows:

William B——, aged thirty, occupation fish dealer, was admitted to St. Francis Hospital January 18, 1887. He uses stimulants freely, and has had gonorrhœa and syphilis.

Six months ago he noticed a swelling in the popliteal space on the right side, which gradually increased in size and for four months past has been extremely painful. On examination a large pulsating tumor was found to occupy the whole of the popliteal space on the right side, extending upward to Hunter's canal. Over the tumor a loud rasping bruit was audible.

Two large angular sloughs were found in Scarpa's triangle, due to compression with the tourniquet before he entered the hospital.

On January 26th he injected a four per cent. solution of cocaine over the site of incision and ligated the femoral artery in the lower part of Scarpa's space, without pain. During the operation, however, the patient became pale and pulseless, and the operation had to be suspended for a few moments in order to administer stimulants. This collapse, he thought, was due to the cocaine.

When the operation was completed the leg was wrapped in cotton and a dose of opium and quinine given. Knowing that the previous attempt to cure the aneurism by compression had produced much sloughing, and being fearful of secondary hemorrhage, he took the precaution to keep a member of the house staff with him, and to place a tourniquet around the limb, ready to be tightened at a moment's notice.

On February 10th, fifteen days after the operation, there was considerable oozing of blood from the lower part of the wound around the ligature, which was stopped by making pressure with the tourniquet.

On the night of the 11th, the tourniquet being loose, a sudden gush of blood took place, which was stopped with the tourniquet by the house surgeon, Dr. Spence, but not before a large quantity of blood had been lost. On February 12th something went wrong with the tourniquet again, and another severe hemorrhage took place, and although the tourniquet was rapidly tightened, the patient was exsanguinated before the flow of blood ceased. The pulse could scarcely be felt at the wrist, there was great thirst which was not relieved by liquids. There were also great restlessness and sleeplessness. The day following Dr. Howe concluded to perform transfusion, and not being able to get blood to transfuse,

he injected into the cephalic vein ten ounces of Little's solution, prepared by the house physician, Dr. Hodenpyl. There was some relief from the collapse by the operation, but on the day following he seemed to be as low as ever, and he opened the same vein and injected *sixteen* ounces of the same solution. This latter injection was followed by immediate and well-marked relief. The pulse became fuller and the voice stronger. The pain in the lumbar region disappeared, and the patient expressed himself as feeling first-rate. There was no doubt about the efficacy of the injection.

The members of the house staff watched the patient faithfully night and day, keeping the tourniquet applied for a period of three weeks. At the end of that time the instrument was removed and no more hemorrhage occurred.

The patient's condition at this time, March 3d, was not good. The leg was œdematous and purple. The knee-joint was filled with liquid, and he was still very weak. He, however, gradually gained flesh and strength, and was discharged from the hospital in May.

There were two interesting points to consider in connection with this case, viz., the origin of the hemorrhage and the success attending the transfusion of nearly two pints of a saline solution instead of blood. The flow of blood was such as could only come from a very large artery. Query: Did it come from the femoral artery? He thought it did. Dr. Shrady, his colleague, thought otherwise, especially because there was no recorded case of recovery after any such accident. If it did not come from the femoral artery, where else did it come from? The blood started at the site of the ligature on the fifteenth day. The patient was exsanguinated by a few seconds' flow.

Then, with regard to the injection of the saline solution, he must say he had no faith whatever in it. He had never employed it before, and he only used it then because blood could not be had. The second transfusion, he thought, without doubt saved the patient's life.

Some time afterward he injected twelve ounces of the same solution into the veins of a boy in the hospital who had phthisis, Pott's disease, and abscess. It did him no good.

Jennings' Solution.—℞. Sodii chlor., gr. l.; potass. chlor., gr. iij.; sodii sulph., and sodii carb., āā gr. ijss.; sodii phosph., gr. ij.; alcoholis, ʒ ij.; aq. dest., Oj. M. et S.: Inject at 100° F.

Little's Solution.—℞. Sodii chlor., ʒ j.; potass. chlor., gr., vj.; sodii phosph., gr. iij.; sodii carb., gr. xx.; alcoholis, ʒ ij.; aq. dest., ℥ xx. M. et S.: Inject at 100° F.

Dr. Howe also presented a specimen removed from a case of femoral aneurism, in which he

LIGATED THE EXTERNAL ILIAC ARTERY UNDER COCAINE.

It was accompanied by the following history:

John W——, aged twenty-one, single, of Irish birth, and a boilermaker, entered the hospital January 18, 1887, complaining of severe pain in the right leg, and especially along the inner side of the thigh. It had begun five days before this, and was accompanied by numbness of the limb and severe pain on attempting to walk.

In September of the previous year he had suffered from an attack of typhoid fever. He had also had several severe attacks of acute articular rheumatism, and for four years believed his heart to have been affected, although he had never suffered from it further than from slight dyspnœa on exertion.

There were no evidences of venereal disease, and no history of alcoholic excess.

On examination the heart was found to be acting strongly; the pulse-rate was about 90. There was a loud mitral regurgitant murmur, and also an aortic regurgitant. The lungs and the abdominal organs showed nothing abnormal. The urine was examined with negative results. Locally, nothing was found to account for the pain. The patient was in a fair general condition, although somewhat anæmic. There was a slight elevation of temperature daily.

On the 25th, the second and third toes were found to be livid, and the whole extremity was cold and somewhat swollen.

On February 1st, a slight swelling was noticed immediately below Poupart's ligament in the line of the femoral artery, and this rapidly increased in size. By the 15th, there was a swelling the size of a hen's egg, which showed pulsation and presented a well-marked bruit. Pressure could not be applied below Poupart's ligament, and was very badly tolerated above.

The circulation had improved in the leg, and there was less tendency to gangrene. The patient's general condition had grown worse, and morphine had to be freely used to secure relief from the pain. He was then transferred to the surgical side of the hospital for treatment. The aneurism still continued to increase very rapidly in size, and on February 27th, scarcely four weeks from its first appearance, the skin over it was livid and softened, and rupture of the sac seemed imminent. Without hope of permanently benefiting the patient, but simply to do away with the danger of sudden death from rupture of the sac, he ligated the external iliac artery, first, however, injecting into the subcutaneous cellular tissue, over the artery, fifteen minims of a four per cent. solution of cocaine. This quantity of cocaine sufficed to make the operation a painless one, excepting at its termination, when the edges of the wound had to be widely separated to get at the artery.

On the third day after operation there was free oozing from the wound, which was opened and a search made for bleeding points. Slight compression was all that was necessary, however, to control it. On the sixth the temperature rose to 104½, and the abdomen became swollen and painful. The ligature came away on the ninth. He grew weaker rapidly, and on the tenth he died.

The autopsy showed the heart to be hypertrophied, and the aortic and mitral valves roughened and covered with vegetations. The pericardial sac contained a large amount of fluid. The lungs were congested. The intestines were distended. In the right iliac region, near the seat of operation, there were some fibrinous adhesions. There was no effusion. Both extremities of the ligated artery showed firm clots.

The points of interest in this case are first, the rapid development of a femoral aneurism in a young, bed-ridden patient; and second, the successful performance of the operation, without pain, by the use of cocaine as a local anæsthetic.

In this connection he wished to state that he had also amputated the mammary gland for scirrhus, in St. Francis Hospital, using during the whole operation forty minims of a four per cent. solution of cocaine. The operation was completed without pain, but at its termination the patient vomited. Whether this was the result of the cocaine or from shock, he was not prepared to say. These are the first cases of the kind on record where cocaine has been used instead of ether or chloroform.

Dr. Wyeth remarked, with regard to Dr. Howe's first case, that it was very unusual for constitutional effects to be developed by the injection of twenty minims of a four per cent. solution of cocaine, and he made this remark because he was so much in favor of the use of cocaine in surgery that he would dislike to have it discarded through fear to employ it. To be sure, it was not impossible for the effect mentioned by Dr. Howe to occur as a consequence of this moderate quantity, but as he had used the drug very extensively for the purpose of producing local anæsthesia, and had seen its unpleasant constitutional effects produced in only one case, and that where a drachm of this solution became actually forced into the tissues, he believed that the cases in which such effects would be produced were very rare.

With regard to

TRANSFUSION OF A SALINE SOLUTION

in Dr. Howe's first case, Dr. Wyeth said he was glad that Dr. Howe had acknowledged his conversion to the use of saline solutions for this purpose. He had had two cases in which he had practised injection of this solution with very marked benefit. One occurred in the practice of Dr. Sims, and the woman became exsanguinated in labor before the doctor's arrival. In that case, Dr. Wyeth injected twelve ounces of Little's solution into the median cephalic vein ; the improvement was immediate, and the patient recovered. It was Dr. Sims' opinion that she would have died, had she not had the benefit of the transfusion. The second case was one of hemorrhage after ovariotomy, in the practice of Dr. Mundé. In that instance twelve ounces of the saline solution were injected at two different times, and both injections improved the condition of the patient immediately and very markedly ; but, despite the benefit, the case terminated fatally.

Dr. Wyeth thought it was now generally accepted by surgeons that there was no better agent for transfusion than the saline solution.

Dr. Howe was unwilling to go so far as Dr. Wyeth in commending the saline solution, for he still believed that

THERE IS NOTHING BETTER THAN BLOOD FOR TRANSFUSION,

and that the saline solution was next best, and that it answered an admirable purpose where blood could not be obtained. Besides, to use the blood of an excited, nervous relative for transfusion was very unfavorable.

Dr. Wyeth presented

A BULLET

thirty-two calibre (Smith & Wesson's), removed from a man in whom it had lain for three and a half years. It passed through, and was followed by collapse and loss of function of, the right lung. It entered the third intercostal space, and lodged in the scapular region. The operation for its removal was performed under cocaine anæsthesia.

The case was made the text for the report of one of

STAB-WOUND OF THE LUNG,

that came under his care one year ago, in a man twenty-eight years of age. He was stabbed five times, and three times the blade entered the left lung from the middle up to the apex. Profuse hemorrhage followed from the wounds and also from the mouth. Collapse of the lung and empyema followed, for which Dr. Hunter McGuire, of Richmond, operated three times by incision into the thorax and drawing off the pus. The patient gradually failed, however, and finally came to this city, when Dr. Wyeth found a circumscribed empyema six by four inches and two inches deep. After the patient was anæsthetized he found that the incisions made by Dr. McGuire failed to give complete relief, because the ribs closed the opening almost immediately, and prevented drainage. Dr. Wyeth excised two inches of one rib, and then carried in a stiff drainage-tube and drained the cavity from the bottom. The patient improved, and, in the course of six months, recovered. The case was interesting because it showed the

NECESSITY OF SECURING PERFECT DRAINAGE.

The cavity was irrigated by varying strengths of a solution of bichloride of mercury, 1 to 3,000, 1 to 1,000, and even 1 to 500; and at times he felt that he was subjecting the patient to considerable risk, but no unpleasant results followed. He used the strong solution for the purpose of killing the pyogenic property of the lining membrane of the abscess cavity. In the Surgical Society stress had been laid on the absorption of a solution of 1 to 5,000 by the flaps after amputation at the hip-joint, so as to produce toxic effects, which he regarded as impossible, and he brought this case up in comparison.

The President said he had often wondered, in looking at pyogenic membranes, which are so distinctly septic, how either weak or strong solutions could be efficacious, because the colonies of micrococci were often so deep in the tissues.

Dr. Wyeth said that it was with the view to reaching the deep-seated colonies that he curetted the surface with his finger-nail, and practically hyper-distended the cavity.

Dr. Putnam-Jacobi suggested that it was not really the antiseptic, but the irritant, action of the strong solution that was obtained.

Dr. Van Santvoord presented

THE EAR AND TEMPORAL BONE

removed from a child aged eighteen months, that had had middle-ear disease of long standing, and died apparently from exhaustion, with marked emaciation.

On opening the skull a small abscess was found under the arachnoid at the root of the seventh nerve, on the left side. There was a sub-dural abscess over the petrous portion of the temporal bone. On opening the ear it was also found that the bone had been formed under the temporal fascia, and that the whole of the petrous portion was necrotic.

The point of special interest was the situation of the abscess with reference to an incision for its evacuation. The usual rule is to make the incision one-fourth of an inch, or perhaps more, behind the ear, but in this case such an opening would have been of no avail, as it was necessary

TO MAKE THE CUT DIRECTLY IN THE CREASE BEHIND THE EAR AND FORWARD.

He regarded this as an important point in connection with the surgical procedure adopted for giving exit to pus in these cases.

Dr. Garrish thought it was proper to trephine in all these cases, when there was evidence of severe inflammatory action.

Dr. Putnam-Jacobi presented a specimen of

DERMOID CYST BY INCLUSION,

removed after death from the body of a woman forty years of age, and the mother of nine children, who was admitted to the infirmary February 11, 1887. She said that her abdomen had been enlarged eighteen years, but that it had not increased in size during the last three years. She had been able to work until three weeks before admission, when she felt that something had ruptured in her abdomen.

On admission, there was found an immense tumor, reaching up to the epigastrium, that had separated the recti muscles, and allowed an umbilical hernia to form. The posterior wall of the vagina was prolapsed, and the cervix uteri was crowded under the symphysis pubis. The circumference of the abdomen at the umbilicus was 58½ inches ; the distance from the umbilicus to the pubis, 19 inches ; from the umbilicus to the ensiform cartilage, 18 inches ; and from the umbilicus to the anterior superior spinous process of the ilium on either side, 19½ inches. The patient failed rapidly and died.

At the autopsy, the muscular walls of the abdomen were found atrophied, and adherent to the peritoneum. This was greatly thickened, and closely adherent to the tumor, and the cavity contained an amber-colored, gelatinous substance, together with much yellow fluid. The tumor was found on the left side, and below the umbilicus. The sac had a large opening with smooth edges at the upper part. At this point the cyst had evidently ruptured at some time, and allowed the escape of the fluid and gelatinous material which filled the abdomen above it. Four or five masses, about the size of hen's eggs, were found attached to the omentum above the level of the tumor, and

contained sebaceous matter and hair. The question arose, whether or not the rupture occurred so late as six weeks before death, when the patient had suffered from a sudden pain in the abdomen, and sensation of something bursting inside? There was then a distinct cyst within the peritoneal cavity to which the peritoneum had become closely adherent. The left ovary could not be found. At the outer part of the tumor the coils of intestine were so closely adherent, and the adhesions were so numerous, that it seemed remarkable that the woman had not suffered from symptoms of intestinal obstruction. The cavity of the tumor was filled with amber-colored, semi-solid fluid, and masses similar to those found attached to the omentum. At one place spiculæ of bone could be distinctly felt, and a portion of a maxillary bone with one well-formed tooth were found. The masses within the sac also contained hair and sebaceous matter. The tumor seemed due to inclusion of germs from a twin embryo, rather than a degeneration of an ovary; for it was only connected with the pelvic organs by a fold of peritoneum, which passed from its lower surface to the upper or posterior wall of the uterus.

The President presented a specimen of

THROMBOSIS OF THE RIGHT AURICLE WITH CENTRAL DEGENERATION OF THE CLOT.

A German bartender was admitted to hospital April 8th. He answered questions reluctantly, and the previous history was therefore incomplete. He was a heavy drinker, and had been jaundiced for five years. There had been no vomiting. He had been in bed for three weeks, and for two weeks had been short of breath. His right arm was swollen, but he would not say how long it had been so. He was considerably jaundiced on admission, well-nourished, his mouth dry and brown with sordes. Respirations were thirty-two; chest expansion, fair. Marked dulness and tubular breathing at right apex, and voice much increased. No râles. Left apex breathing and voice increased.

Heart-apex fifth space, three inches from median line, regular, fair force, no murmur. There was marked subcutaneous œdema of the right arm and hand from neck downward. Nothing abnormal could be detected in the veins of the arm. There was a little œdema in the under-part of left arm and forearm, but none in shoulder or hand.

Pulse ninety-six, feeble, regular, rather high tension. He was in a state of low delirium, and died on the day following admission.

Autopsy.—Right auricle and ventricles moderately dilated. Valves normal. In the right auricle, just beside the entrance of the descending vena cava, and somewhat encroaching upon it, was a white, smooth-surfaced, globular, projecting thrombus, about one inch by three-fourths inch in diameter, closely adherent to the auricle wall by a broad base which quite filled up the cavity of the auricle.

The wall of the auricle at the seat of adhesion of the thrombus was rough on the inner surface, and the seat of several small areas of necrosis, while the muscle-fibres in this vicinity were in places necrotic, and markedly fatty. The central part of the thrombus was softened and formed a whitish semi-fluid mass which had the gross appearance of pus.

The central softening was so extensive that in places a thin wall only remained, enclosing the detritus. This softened material was found, microscopically, to consist of fragments of red and white blood-cells—the latter mostly fatty—and granular and fatty detritus.

Aside from a large central area of softening, the thrombus showed similar smaller areas in these parts, which were entangled among the projecting muscle-bundles of the auricle.

The subclavian and jugular and the veins of the arm appeared normal, as did the larger vessels of the lungs. The upper half of the right upper lobe of the *lungs* was the seat of excessive congestion and œdema. The posterior half of the lower lobe showed moderate congestion and œdema. The left lung showed moderate congestion and œdema of the posterior part of both lobes. There was general chronic bronchitis. The *liver* showed chronic congestion with chronic interstitial inflammation, both in moderate degree. The gall-ducts were patulous, the gall-bladder empty. *Kidneys* normal.

The thrombosis appears to have been secondary to a localized endo- and myocarditis of the auricle, of a necrotic form. The cause of the apparently primary lesion, he was unable to state.

He presented the specimen chiefly because it was so excellent an example of the lesion which has become classical under the name of the "globular thrombus" of Laënnec, and to show how thin and fragile may be the still firm portion of such a clot, which is all that retards the occurrence of multiple embolisms, and an increased complexity in clinical symptoms already obscure.

Dr. J. Lewis Smith presented, in behalf of Dr. W. P. Northrup, specimens from a case of

MEASLES COMPLICATED BY BRONCHO-PNEUMONIA AND VERY MARKED PARENCHYMATOUS NEPHRITIS,

occurring in a child aged two years and three months.

Dr. Garrish exhibited microscopic sections of

A DISEASED KIDNEY OF THE HORSE.

The Society then went into executive session.

OUR PARIS LETTER.

(From our Special Correspondent.)

INTERNATIONAL CRIMINALITY—WHY SUICIDES CAN CUT THE THROAT WITHOUT MUCH PAIN.

Paris, July 28, 1887.

In an article by Dr. Lacassagne, a distinguished medico-legist, on "International Criminality," the author asserts that "criminality is submitted to fixed laws which vary according to the period, the physical and social surroundings, food, heredity, race, etc. These oscillations are neither the work of chance nor of spontaneous caprices; experimental method has scientifically disposed of these utopies on which a hundred generations of metaphysicians have fruitlessly cavilled." The author further asserts that crimes against persons are in direct ratio, and crimes against property in an inverse ratio, of the elevation of the temperature and of the length of the day. He also demonstrates, by curious graphical sketches, that crimes against morals always attain their maximum in the months of May, June, July, and August. This observation has given birth to a branch of science termed "criminal sociology," which has for its aim the objective study of the criminal world, and the research of causes which engender crime.

M. Lucet, a literary author, writing on the same subject, furnishes very useful information. It comprises eight States: Italy, France, Belgium, Germany, England, Austria, Hungary, and Spain. He divides international crimes into three principal categories: Homicidal. In this class Italy takes the lead, for in 100,000 inhabitants there are 9.53 condemned; then follows Spain, with 8.25; Hungary, with 6.73; Austria, with 2.44; France, with 1.54; Belgium, with 1.44; Germany, with 1.12; England, with 0.71. In the category of wounds Austria is at the head, having 230.96 condemned for 100,000 inhabitants. Belgium comes next, 175.40; Italy, 155.20; Germany, 126.40; France, 64.41; Spain, 23.18; England, 6.83. As regards immoral assaults, Germany and Belgium, according to the author, dispute rather closely the little enviable priority, for the former shows a proportion of 14.07, and the latter 13.87 condemned. France stands next, with 10.26 for 100,000 inhabitants. Then follows Austria, with 9.33;

Hungary, 6.89; Italy, 4.01; Great Britain, 1.31; Spain, 1.03. For theft Germany and England take the lead. Germany furnishes 226.08 condemned out of 100,000 inhabitants; Great Britain, 166.62. Of this number Ireland furnished 65.82; England, Scotland, and Wales furnishing the remainder. Information had not been received from Austria on this point; Italy gives 165.89; France, 110.96; Belgium, 90.44; Spain, 59.64; Hungary, 58.56 for 100,000 inhabitants.

That these facts should have an absolute value, it would be necessary to know, in the relative statistics of each nation, the proportion of habitual criminals. According to M. Lucet, the increase of the latter proves nothing in favor of the weakness of the general morality in the midst of a given collective number. He states that one must, on the contrary, conclude that the current perversity accumulates in a sort of purulent collection which serves as a derivative, and lodges itself within the limits of a group of people, that of malefactors by profession, whereas, by a phenomenon analogous to the economical phenomenon of division of work, the remainder of the population becomes refined and improved. It may, however, be deduced, concludes the author, from the irrefutable statistics given above, that "our good friends of London and Berlin will be very wrong for the future to load with contempt and malediction the modern Babylon, as it is called."

It has often been a subject of wonderment how it is that individuals, wishing to destroy themselves, can cut their throats to the spine, and sometimes even inflict on that part several deep wounds, without any apparent suffering, which would imply a courage almost superhuman, owing to the excessive pain that is supposed to be caused by the wounds. In a recent communication to the Academy of Sciences, Professor Brown-Séquard endeavored to give an explanation of this fact by experiments on animals, when he ascertained that an incision, even slight, of the skin of the neck, particularly in the neighborhood of the larynx, is sufficient to destroy sensibility in at least two-thirds of the anterior part of the neck, and often still further. These experiments were performed in reference to the triple murder that has been lately committed in Paris, where the victims did not appear to have suffered much pain, although they had their throats cut to the spine, for no cry had been heard. This circumstance would explain how it is that individuals who attempt to commit suicide by cutting the throat are not deterred by pain from the completion of their design. When the larynx is cut, complete anæsthesia, according to the eminent physiologist, is produced. The skin of the neck possesses, as the larynx, though to a less degree, the power of inhibiting sensibility; and the larynx, the trachea, and perhaps the skin that covers them, possess the power of causing death under a sudden mechanical irritation, in the same manner as the spinal bulb, and thus suddenly arrest the great functions of the nervous centres as well as those of respiration and circulation. Several individuals who have committed suicide by hanging have perished, not by asphyxia, as may be supposed, but by syncope determining the arrest of the heart and of the circulation. At the autopsy, instead of finding dark blood in the arteries, as after asphyxia, the blood has been found red; death is produced by nervous shock.

This scientific revelation might be taken advantage of to recall to life people partially asphyxiated by galvanizing the skin of the neck. This proceeding, according to Brown-Séquard, will prove more efficacious than insufflation of air into the lungs. If electricity can render service in the case noticed above, it very often causes death, particularly since electric lighting necessitates the employment of conducting wires at times very long. Electricity, then, kills by direct action, by the destruction of the tissues, or by reflex action, in producing various lesions. For the most part there is an arrest of the respiration, which produces asphyxia. In this case artificial respiration might bring to life an individual struck by lightning.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 31 to August 6, 1887.

SUTHERLAND, CHARLES, Colonel and Surgeon. Leave of absence extended one month. S. O. 174, A. G. O., July 29, 1887.

FRYER, B. E., Major and Surgeon. Relieved from further duty at Fort Lowell, Ariz. S. O. 176, A. G. O., August 1, 1887.

BROWN, HARVEY E., Major and Surgeon. Relieved from duty in Department of Missouri, and ordered to Jackson Barracks, La., for duty at that post. S. O. 174, A. G. O., July 29, 1887.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. Granted leave of absence for one year on surgeon's certificate of disability. S. O. 177, A. G. O., August 2, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 6, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	39	9
Scarlet fever	32	6
Cerebro-spinal meningitis	2	2
Measles	30	4
Diphtheria	82	23
Small-pox	6	1
Yellow fever	0	0

IN THE SURGICAL CLINICS AT STRASSBURG.—Naphtholin, a white powder with a peculiar, disagreeable odor, which was formerly used as the antiseptic in the dressings of all wounds, has been discarded. As far as its antiseptic properties were concerned, Professor Luecke was entirely satisfied with it, but it irritated the skin, and in the majority of cases caused an eczema which was very difficult to cure. Therefore it is no longer used, and now carbolic acid, iodoform, and solutions of corrosive sublimate have taken its place. The starch-bandage, which was at that time always used as the external covering upon all large dressings, is still frequently applied. It gives a stability to the dressing which is very comfortable both to patient and surgeon.—*Cor. Cincinnati Lancet and Clinic.*

INEBRIETY IN AMERICA.—Dr. Crothers traces the origin of the American recognition of inebriety as a disease to Dr. Benjamin Rush, and the first practical application of treatment in a special home to Dr. J. E. Turner, of Maine. There are now fifty different hospitals for inebriates in America, with over one thousand patients, besides about one thousand under treatment in private families and other surroundings.

OSTEOTOMY OF THE PELVIS.—In a letter from Dr. Senn, in the *Journal of the American Medical Association* (May 7, 1887), mention is made of a new operation proposed by Macewen. The latter claims that his experiments have demonstrated that section of the pubic bone, an inch and a half or two inches from the symphysis, and of the ascending ramus of the ischium, would add one and a half inch to the antero-posterior diameter of the pelvis. By such an operation, in cases of difficult labor from contracted pelvis, Macewen proposes to do away with the much more serious operation of abdominal section.

INTRA-PERITONEAL HÆMATOCELE CONSIDERED AS A CONSEQUENCE OF RUPTURED TUBE-PREGNANCY, WITH REPORT OF A CASE.[1]

BY CHARLES A. L. REED, M.D.,

PROFESSOR OF SURGICAL DISEASES OF WOMEN IN THE CINCINNATI COLLEGE OF MEDICINE AND SURGERY, AND OF CLINICAL GYNECOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF CINCINNATI; FELLOW OF THE BRITISH GYNECOLOGICAL SOCIETY, ETC.

Two years ago, I invited the attention of this Society to the surgical treatment of *extra*-peritoneal hæmatocele. I then urged that, in a vast majority of cases, the extravasation should be left alone, as absorption would take place; but that in certain other cases, such as recurrent hemorrhage and suppuration, of which I gave an illustrative instance, the bleeding-point should be controlled by laparotomy. This year, I beg to call your attention to *intra*-peritoneal hæmatocele, and to urge precisely the same central idea in treatment. If it were necessary to offer any excuse for presenting this subject, other than its inherent surgical importance, it would be that in England the whole question is not only a moot one in scientific circles, but has recently figured as a problem in medical jurisprudence. In this latter relation the question raised was, essentially, should the uterine appendages be removed on the affected side in cases of intra-peritoneal hæmatocele? And if so, why? The answer given was in the affirmative, because, it was alleged, that in the cases operated upon the hæmatoceles resulted from ruptured tubal pregnancies, and that the extravasation was perpetuated by a bleeding-point in the rent in the tube. It is my purpose to devote this paper to a partial discussion of this relatively new postulate in abdominal surgery, rather than to a systematic study of accumulations of blood within the peritoneal cavity.

In examining the early literature of this subject, one is struck with the fact that writers on tubal pregnancy never failed to speak of rupture of the sac as a fruitful cause of hemorrhage into the abdominal cavity; yet, when they began to discuss this latter condition under the head of hæmatocele, they almost invariably failed to speak of tubal pregnancy as an etiological factor. This, indeed, is true of a large number of our modern authors. If, therefore, we desire to get the views of authors, early or modern, on this important question, we have to examine their utterances under the head of tubal pregnancy rather than hæmatocele. This holds true of Duverney's case, recorded as having occurred as early as 1712. It is stated by Mr. Lawson Tait,[2] in the "Ingleby Lecture" for 1886, that Bernutz,[3] in 1848, was the first to recognize the causal relationship existing between tubal pregnancy and hæmatocele, and to indicate the proper line of treatment, viz., laparotomy and ligature. I am disposed to accept this claim for Bernutz, so far as it relates to a suggestion of treatment; but I must insist that all the *essential conditions* of intra-abdominal accumulations of blood from ruptured tubal pregnancy were recognized and described[4] by one of Mr. Tait's own countrymen, Dr. John Burns, of Glasgow, as early as 1814. It is true, Burns does not use the word "hæmatocele," which was coined by Nélaton a quarter of a century later, and which is such a positive misnomer that it had better never have been coined at all.

Burns, however, said that "the sac might burst and the patient die from hemorrhage." He clearly described the subsequent changes when he said that "irritation is produced, inflammatory symptoms supervene, and hectic takes place." He still further indicated his insight into these cases when he said of them that "the most frequent termination is that by inflammation ending in abscess." And I know no better way to round out a description of what is now known as hæmatocele than by employing Burns' observation that the suppurating contents of a burst tubal pregnancy "might be enclosed in a kind of cyst of lymph." Blundell,[1] writing in 1830, recognized the same condition, and said that he did not doubt that "many women die in this way, but, being buried without examination, the real cause of their death is never ascertained." He even went so far as to *mention* the expediency of abdominal incision for the control of the hemorrhage, but doubtless under the pressure of the mediæval conservatism of Guy's Hospital—a conservatism which still exists in that institution—he abandoned the idea, leaving it to be again suggested by Bernutz thirty years later, and finally to be realized by Mr. Lawson Tait after the lapse of a half-dozen decades. Between Blundell and Tait, numerous writers touched upon both topics, but relatively few of them recognized that tubal pregnancy caused intra-peritoneal hæmatocele. As soon as Nélaton, and, subsequently, Bernutz and Goupiel, began to write upon hæmatocele, the profession appeared to drift away from the definite etiology and pathology so clearly outlined by John Burns, until latter-day authors attribute the condition to almost every other than what I believe to be the one most fruitful cause. One of them,[2] while not entirely ignoring tubal pregnancy as a cause, manages to so hide it under glittering generalizations that the obscuration amounts to a negation. Thus we are told that hæmatocele may come from: "1, Reflux of blood from the uterus; 2, direct outflow from the pelvic or lower abdominal blood-vessels; 3, metastasis, or transudation in certain blood diseases." Of these three general conditions the second is, to my mind, the only one not open to the most rational doubt. The valve-like arrangement of the tubal endothelium is sufficient to subject the first proposition to a fatal uncertainty. I entirely agree with Emmet,[3] that the "contents of a distended uterus never pass into the peritoneal cavity unless by rupture of that organ itself or of the uterine portion of the tube, which may have become dilated." The metastatic doctrine, considered in this relation, lacks that confirmation which would justify us in saying that the extravasation is anything else than "a direct outflow from the pelvic blood-vessels." It strikes me that this classification must finally resolve itself under the one head. But why should the lower abdominal or pelvic blood-vessels rupture? I am aware that, as a consequence, generally, of repeated and frequent pregnancies, the intra-pelvic veins sometimes become varicosed; and that, under the pressure of premenstrual congestion, pelvic inflammation, or mental shock, they sometimes rupture, but in that instance the escape of the blood is beneath the fold of the broad ligament and, consequently, extra-peritoneal. And here I want a word about an extra- becoming converted into an

intra-peritoneal hæmatocele. It strikes me in view of the ease with which the peritoneum can be peeled off the pelvic and abdominal walls, that it would yield its normal adhesion rather than rupture in its continuity to accommodate the pressure of the increasing clot. As a consequence, I believe that the cases are few and far between in which the peritoneum ruptures from the mere force of the circulation, and permits a clot which had formed outside of it to escape into the abdominal cavity. I have been forced to this view by several cases[1] of extra-peritoneal hæmatocele upon which I have operated, and in some of which the peritoneum was pushed as high up as the umbilicus. In these instances the resistant power of that membrane was put to the test, and not found wanting. In one case, in particular, the rupture and extravasation were the results of mental shock occurring at the menstrual period; but in that case, in which the accumulation was the largest I have ever seen or read of, the peritoneum did not rupture. It is not designed by this evidence, which is far too limited to serve for general conclusions, to deny, much less to disprove, the doctrine that hemorrhage from veins situated outside the peritoneum may cause, primarily, extra-peritoneal hæmatocele and, secondarily, by rupture, intra-peritoneal hæmatocele; but it is designed to prove that these varieties are not so easily convertible as some authors, as, for instance, Emmet, would have us believe, and that when accumulations of blood occur within the peritoneal cavity, the strong probability is that they result from hemorrhage directly into that cavity. If, now, we grant the existence of tubal pregnancy and consider the bursting of the sac, we can understand how, in at least the vast majority of such cases, the resulting hemorrhage would be intra-peritoneal. And, if we go a step further and consider the demonstrated frequency of inflammatory disease of the Fallopian tubes, the resulting destruction of the endothelium, the consequent facility with which the spermatozoa may pass into the ampulla, the fecundation of the ovum and fixation of the products of conception at that point, we can understand why tubal pregnancy is of much more frequent occurrence than was formerly supposed. We can readily understand, too, how the fanciful classifications of the origin of the blood, which we have quoted, come to be reduced to the one head, viz., "rupture of the lower abdominal or pelvic blood-vessels," and how, in the particular of intra-pelvic hæmatocele, such rupture probably depends, in the majority of instances, upon the existence of tubal pregnancy. I have called attention to Harris' classification because he is one of the ablest writers in America, and because it is teachings such as his that have led the profession away from what later experiences are proving to be one of the most fruitful and, until very recently, one of the most fatal causes of pelvic hæmatocele, and that have, as a consequence, diverted attention from what, in the light of modern surgery, is the only rational treatment of the condition.

It is fortunate, however, that the other side of this important pathological question has not been entirely neglected. From the time Blundell, in 1830, and Bernutz, in 1848, guessed at the nature of these cases and suggested the expediency of abdominal section for the control of the progressive hemorrhage, there was no one to put the suggestion into practice until Mr. Lawson Tait,[2] in 1881, at the urgent solicitation of Mr. Hallwright, of Birmingham, did the operation. It was the beginning of a new era in the intelligent understanding and management of these hitherto intractable cases. Prior to that time the mortality was almost one hundred per cent.; since that time I have heard of no one losing a case subjected to Mr. Tait's line of treatment, except in one instance, and that was a case in Mr. Tait's own hands. The pathology upon which the treatment was based, and which has been confirmed by the revelations of the treatment itself, has, however, been more generally accepted than has the practice. Schroeder,[1] J. Veit,[2] and Kirrisch[3] are among the leading Germans who agreed with Fritsch,[4] that "the most frequent source of the hemorrhage is the ruptured ovisacs of a tubal or other extra-uterine pregnancy." Among gynecologists, Tait, Imlach, Berry Hart, Thomas, and Emmet are among the most conspicuous who concur in the doctrine, while among the obstetricians, Lusk, Parvin, Barnes, Galiban, and Playfair may be mentioned; indeed, it appears that among those who are the closest students of this question there is practical unanimity that tubal pregnancy is the most common cause of intra-peritoneal hæmatocele, but, as I have intimated, there is less unanimity on the subject of treatment. Why there should be variance on this question, when there is practical agreement on the more primary and fundamental one, is not apparent, unless we shall find that different constructions are placed upon those pathological changes which take place subsequent to extravasation. To my mind those changes were described with great fidelity to truth, if not to details, by John Burns, already quoted. There are, however, several points of difference between later writers. Thus Fritsch[5] says: "The blood in the peritoneal cavity does not remain fluid, but coagulates very rapidly." Tait[6] says: "When blood flows in quantity into the peritoneal cavity, probably by reason of its dilution by the lymph always present there and easily excited into excessive flow by any abnormal condition, it does not show much tendency to coagulate save in a very fitful and fragmentary way." This is a starting-point of a further divergence culminating in the matter of treatment. Fritsch says: "The operative treatment of hæmatocele has given very bad results." Tait says of his first twenty cases operated upon, "The recovery has been complete and permanent." If we study the pathological changes subsequent to rupture, we have to take into consideration severale lements, viz.: 1, The blood; 2, the fœtal structures; 3, the placental tissue; 4, the lacerated tube; 5, the peritoneum. My own experience accords with that of Imlach and Tait, that the blood remains largely liquid; I am, however, so thoroughly convinced of the absorbent power of the peritoneum that I believe it would take up the extravasated blood were it not for one or both of two conditions, viz., continuous hemorrhage and suppuration. But here are precisely the occurrences which interfere with the spontaneous cure of the vast majority of these cases. Interpreted in the light of well-known pathological laws, the changes which take place are as follows, viz.: Suppuration begins with the fœtus, which, by being deprived of the environment necessary for its growth, dies; the blood is the next to yield, and the placenta last. If we consider the necessary death of the fœtus, I do not see how we can expect to get along for any considerable time in these cases without having pus; although the failure to find remnants of fœtal tissue in certain instances shows that suppuration may either be deferred until after absorption of the embryo has become more or less complete, or that it has the power to completely disintegrate the, as yet, almost protoplasmic products of conception. The behavior of the peritoneum is different at different stages; thus, immediately after rupture of the tube, the blood and fœtus, like any other foreign bodies or irritants, provoke it to increased vascularity, and there is a temporary transudation of serum; if, however, suppuration does not ensue, the vascularity of the membrane accommodates itself to the new conditions, the serous flow ceases, and the absorbent function begins to be exercised. But let tissue-disintegration begin in the fœtal structures, and, as a consequence, suppuration ensue in the exuded blood, the behavior of the peritoneum is changed at once—vascular-

ity leaps at a bound to inflammatory stasis; a stream of serum is thrown out; cell-proliferation takes place on the surface; plastic lymph is exuded; proximal surfaces become agglutinated, and the suppurative process becomes temporarily limited by a sort of provisional encystment. But we have omitted to speak of the Fallopian tube; what has it been doing? With a rent in its continuity it has been adding to the volume of blood already extravasated, and this addition goes on, because of the lax condition of the tubal walls themselves, because of the non-resistant power of the exuded clot and of the neighboring intestines, and, finally, because of the enlarged condition of the vessel itself. With the volume of blood gradually increasing, with the product of rapid cell-proliferation, and with the increasing volume of exuded serum all added to the temporarily limited mass of suppuration, the pressure is increased, the peritoneal adhesions yield, the pus is brought in contact with a denuded and now absorbent surface, and septicæmia results; or, suppuration aside and the hemorrhage alone progressive, what other result than ultimate exsanguination can be expected? What wonder that, under the old let-alone régime, the mortality in these cases was almost universal?

With this pathology as the guide, the duty of the surgeon with regard to treatment is, to my mind, obvious. It is merely an application of that general law of surgery which, as formulated by Tait and applied to these cases, is as follows:[1] "For surgical hemorrhage, cut down and tie the bleeding-point; if a big branch of the femoral artery were bleeding, my colleagues who deal with such cases would cut down and tie it. Why should Poupart's ligament be a line of demarcation within which this writ will not run?" Bernutz and Goupiel[2] say: "The indication in such cases is plain—we must stop the hemorrhage." No person, I fancy, who properly realizes the situation in these cases will deny the propriety of the proposition; but it occurs to me that there are other indications than hemorrhage for surgical interference—the damaged tube, the fœtal structures, and the placental tissue demand attention. Of the latter two it may be said that, even though they become incapsulated and partially absorbed and the residue remain innocuous, they cannot be considered in a surgical sense other than as foreign bodies, and, as such, constant menaces to the health and life of the patient. The tube of necessity becomes destroyed as an oviduct, and, if left intact, it will only be to figure at a later period as a hæmato-salpinx or a pyo-salpinx, and consequently to ultimately demand extirpation. Not losing sight of the fact that some of these cases do well—*i.e.*, the patients live when left alone—the rule remains, that laparotomy is demanded by four considerations, viz.: (1) To control the hemorrhage; (2) to remove the products of conception; (3) to extirpate the tube and, of course, the ovary; and (4) to remove the elements of sepsis. It would be well in this connection to mention certain conditions under which I would question the expediency of removing the appendages. I allude to those cases in which the tube and ovary have become adherent to the adjacent parts (and they are generally in this condition), and in which suppuration has already taken place (which is relatively less frequent). To tear the tube and ovary away under such circumstances would be to expose the patient to the dangers of septicæmia by bringing purulent material directly in contact with a raw and absorbent surface. In these cases I would control the hemorrhage by passing a deep ligature through both folds of the broad ligament, precisely as I recommended in my former paper should be done in cases of intractable extra-peritoneal hæmatocele.

For the purpose of illustrating the foregoing principles, I beg leave to call your attention to the following case:

Mrs. H——, aged thirty-nine, became pregnant in March last. She missed twice. Not desiring children, she took an abortifacient of some sort. A few days later she called in a physician to control a metrostaxis. She deceived him as to the exact nature of her case, which now took a different turn. The metrostaxis ceased, but she was seized with violent pains low down in and to the right of the pelvis, and she fainted twice during the day. A few days later she called in Dr. H. E. Twitchell, of Hamilton, to whom she gave a history of recent rigors followed by high temperature. He found a tumor occupying Douglas' cul-de-sac, which he took for the fundus of a retro-displaced uterus. Coupling these physical conditions with the history of abortion, he concluded that the conception was dead, but that, owing to the position of the uterus, it had not been discharged, and that the clearly septic symptoms were of intra uterine origin. He sent for me to relieve the uterus of its contents. On my arrival, May 6th, I found, in addition to the foregoing physical conditions, diffuse tumefaction in the pelvis, the cervix well forward under the pubis, a tender and tympanitic belly, and a temperature of 104° F. The condition was so like what I have seen in retroflexion of the gravid uterus that I was disposed to accept Dr. Twitchell's diagnosis. The inflammatory symptoms were so great, however, that I concluded to give the patient some opium and quinine, pack the vagina with a tampon of glycerine and tannin, and wait until the next day.

May 7th.—The tenderness had so far subsided that it was deemed expedient to try to evacuate the uterus. The sound introduced as a guide did not, however, turn backward into the supposed retroflexed fundus, but followed the ordinary course three and one-fourth inches. A curette-forceps was now introduced, and numerous shreds of decidua were removed. Bimanual examination now enabled me to make out the womb and the retro-uterine mass as two separate bodies. Around this central fact the whole history of the case now took shape, and a diagnosis of tubal pregnancy, with resulting hæmatocele and abscess, was pronounced. Laparotomy was done the same afternoon, Drs. Twitchell, Skinner, and Fitton present and assisting.

A two-inch incision was made. The peritoneum was found stained with blood, studded all over with patches of exudation-lymph, while all proximal surfaces were agglutinated. On introducing my finger, and passing it toward the cul-de-sac, I found myself breaking up these adhesions, which were but slightly resistant, until presently it appeared to drop into a sort of cavity. Fetid pus, semiliquid blood, shreds of fœtal tissue, and placental *débris* now came welling up through the incision. Sponges were introduced to limit the diffusion of this septic material; and an attempt was made to pump out the remainder with aspirator-tube, but failed. I now introduced sponge after sponge, throwing each one away as I removed it, until they came back coated with laminated placental tissue rather than blood or pus. Recourse was now had to flushing, and pitcherful after pitcherful of water was thrown into the abdomen. Not satisfied with this, I drew out the intestines, carefully mopped them off, returned them, and again flushed. A sponge now removed showed a fresh blood-stain, and I felt that I yet had a bleeding-point to deal with. The tube was, however, firmly adherent, and I felt that to tear it loose would expose its site to infection from some possibly remaining pus. I consequently satisfied myself with ligating through both folds of the broad ligament, leaving the tube within the silk. I again flushed, introduced a drainage-tube, and closed the abdominal incision. The patient was put to bed; her temperature before the operation was 104.4° F.; she now had a rigor, which I attributed to shock; after this the temperature again went to 104° F., but speedily came down to 99°.

The after-treatment consisted in Bantock's method of irrigating the cavity every two hours with a solution of sulphurous acid, beginning with one part in twenty of water, increasing the strength finally to one in five. In the

[1] Lancet, October 30, 1886.
[2] Diseases of Women, p. 202. New Syden. S c.

early stages of the case I added twenty-five per cent. of glycerine, my object being to favor the exosmotic action of the tissues and thus render absorption the more improbable. Considerable pus was washed out each time for several days. No opium was given. On the fifth or sixth day, however, the temperature ran up to 103°, occasioned, as might have been expected, by the development of an abscess in the primary incision; this, however, was opened by Dr. Twitchell, who obliterated it with a single application of powdered salicylic acid. At the end of the third week drainage was discontinued, the sinus in the abdominal wall being kept open by a pledget of cotton. A few days later the patient had a rigor, and her temperature ran up nearly to 104°. Dr. Twitchell promptly reopened the channel with a bullet-probe, and removed a very perceptible quantity of pus from the original sac. The sinus was now further dilated by slippery-elm tents passed the whole length, when a drainage-tube was reintroduced, and the case treated as before. From this point she made an uninterrupted recovery.

This is but a single contribution to the record of laparotomy for the relief of conditions which, prior to 1881, were almost uniformly fatal. From that time up to the date when Mr. Tait sent the fourth edition of his book to press (1883), he had operated upon twenty cases, with twenty recoveries, while in his "Ingleby Lecture," already quoted, he says: " . . . between January, 1883, and July, 1886, I operated upon twenty-five cases, saving twenty-four of them, a very striking contrast to the old plan of letting them alone to die." Dr. Francis Imlach, whose brilliant record entitles him to recognition as one of the pioneers in this extension of abdominal surgery, told me, when I was with him recently in Liverpool, that he had done sixteen cases, with sixteen recoveries. I have not had time to examine the serial literature for the further record of this operation, although I believe that in England, Bantock, of London; Greig Smith, of Bristol; and Sinclair, of Manchester, have been identified with it. But take the brief record that I happen to have at hand, and that is presented herewith, and we have sixty-two cases operated upon, with only one death. Where, in the annals of extra-uterine fœtation, is a similar record to be found in the let-alone policy?

Let me conclude this paper, which is already too long, with the following summary: (1) Intra-peritoneal hæmatocele is an intra-peritoneal accumulation of blood. (2) Ruptured tubal pregnancy, the most common form of extra-uterine fœtation, gives rise to an accumulation of blood within the peritoneum. (3) In consequence of the fluid condition of the extravasated blood and of the yielding character of the adjacent tissues, the hemorrhage has a tendency to continue. (4) In consequence of the death of the fœtus, there is developed a marked tendency to suppuration. (5) In consequence of becoming a foreign body, the product of conception, even though it become encysted, is a constant source of danger. (6) The damaged tube, if left *in situ*, can serve no other than a pathological purpose. (7) Laparotomy is therefore called for to (*a*) control progressive hemorrhage, (*b*) to remove dangerous *débris*, (*c*) to extirpate worthless appendages, and (*d*) to overcome septic conditions. (8) Extirpation of the appendages should not be practised when adhesions are firm, and free pus exists in the sac. I was taught this lesson some years ago by losing a patient from pyæmia in which the pus, discharged from an infinitesimal cyst which was accidentally ruptured, had been absorbed by the raw surface from which an adherent ovary and tube had been torn. (9) In cases in which the appendages are left, the bleeding, if slight, may be controlled by the styptic influence of the sulphurous-acid irrigations, or, if considerable, by deep ligature of the broad ligament. This is the expedient which I suggested to this Society in a former paper. I had occasion to apply it first for the control of intractable hemorrhage in a case in which I had enucleated a very large intra-ligamentous cyst of the ovary, and I did it last in the case reported in this paper. The observance of these rules will, I believe, result in the highest success of a line of treatment the adoption of which is demanded by the revelations of pathology and the dictates of modern surgery, and the vindication of which is to be found in the brilliant record which it has already scored.

MORBUS BASEDOWII.[1]

(Exophthalmic Goitre; Graves' Disease.)

By FREDERICK PETERSON, M.D.,

First Assistant Physician at the Hudson River State Hospital, Poughkeepsie, N. Y.

It is now over forty years since the acute Dublin observer reported three cases of females afflicted with a disease which, in England and France, bears his name. They had symptoms very much alike, viz., violent and long-continued palpitation of the heart, enlargement of the thyroid gland, and protrusion of the eyeballs. Graves noted that the size of the thyroid was variable, that the pulse was singularly rapid at all times, and that there was great disproportion between the beating of the radials and carotids, that of the latter being much more violent than that of the former vessels. But shortly before him had the Merseburg physician, Von Basedow, described the same disease still more accurately. Hence most of the continental nations call the malady by his name. A common, but hardly a proper, term for it is exophthalmic goitre. During the past forty years the literature of the subject has become very extensive.

This disorder is now generally classed among the nervous diseases, although its precise pathology is still far from being known. Benedikt, for instance, places its seat somewhere in the medulla oblongata, Filehne in the restiform body, Geigel in the sympathetic spinal centres, and Eichhorst somewhere in the sympathetic nerve. Charcot considers it a general neurosis allied to hysteria. Few now believe it to have any particular relation to anæmia and chlorosis, more than one of coincidence. But pathologists have not as yet discovered any constant characteristic lesions in the nerve-paths, although many have examined them carefully. The gross pathological changes are in the thyroid gland, heart, and orbits. In the gland are found aneurismal and varicose dilatations of the arteries and veins, with hyperplasia of the glandular substance and its connective tissue as a result. The heart, as might be expected from its laborious action for long periods of time, becomes more or less hypertrophied, and sometimes dilated. Occasionally other lesions, apparently casual, of an inflammatory, degenerative, or valvular nature, are found. The exophthalmia diminishes post mortem, and seems to depend chiefly upon the distention of retro-bulbar blood vessels, together with some œdema or deposit of fat in the orbital connective tissue.

Twice as many women as men are afflicted with the disease, and usually between the ages of fifteen and thirty; but occasionally even very young children or aged people may suffer from it. As to constitution, blond, hysterical, nervous, blue-eyed people are more particularly subject to it. Climate probably has no influence over it, although Eichhorst and others aver that it has. Heredity, however, plays a rôle here, as in so many other nervous affections. Although but few cases are recorded where more than one member of a family has had Basedow's disease, many have been described where other hereditary neuroses existed in other members of the family. For instance, in the case I shall presently describe of Basedow's disease conjoined with insanity, the father died insane.

The etiology is obscure and manifold. As causes have been mentioned mental shock, such as fright, grief, excitement, and physical strain, injury, or weakening diseases.

[1] Read before the Medical Society of the County of Dutchess, June 8, 1887.

The three cardinal symptoms merit here more particular description, and in the wonted order of their development:

I. The frequency of the heart-contractions is from 110 to 120–150 per minute, sometimes even countless. The palpitation is often very painful and accompanied by dyspnœa. Very exceptional cases have been described where the heart's motions were retarded. Percussion will often reveal hypertrophy or dilatation, and auscultation often a systolic bruit of no grave significance, which is also audible over the large vessels of the neck and thyroid gland, and even the whole aorta, and may give rise to a suspicion of aneurism. Sometimes there is mitral insufficiency due to dilatation, or other serious lesions which may be regarded as accidental. The violent action of the heart may not only make itself visible in the arteries, but even distant veins may exhibit pulsation.

II. The swelling of the thyroid gland may be rapid or slow, to considerable dimensions, or not take place at all. Its increase in size is secondary to the acceleration of the heart-movements, and may not appear for months or years after the cardiac symptoms; for the malady is essentially chronic in its nature. Sudden development is exceptionally rare. The struma is seldom large, and generally the right lobe is larger than the left. That it pulsates at times has already been mentioned.

III. The protrusion of the eyes is the third symptom in the order of evolution. It is sometimes more marked upon the right side. The exophthalmia can exist in various degrees, from a slight separation of the lids when the eyes are closed, to almost complete luxation of the eyeball from its socket. It is rare that ulcerations of the cornea occur on this account. Von Graefe pointed out the lack of co-ordination between the movements of the eyeball and upper lid in this form of exophthalmia. He thought it always present; but it is doubtful if it is pathognomonic. Other disorders of the eye found in a case of Basedow's disease may be considered coincident only.

Charcot has found in some cases another symptom, viz., tremor of the muscles in general, or of groups of muscles. Marie thinks that tachycardia and tremor would be sufficient alone for the diagnosis of the disease. Various other neuroses can be concomitant, such as chorea, neuralgia, and paræsthesia. Sometimes there is a tendency to increased secretion from the skin, kidneys, and salivary glands, while nosebleed is common, and hemorrhages from the lungs and bowels occasional in the disorder. Amenorrhœa is frequent.

Changes in the skin, due to altered tissue-nutrition, have been noticed, such as sclerema, bronzing, urticaria, and vitiligo, and from similar causes even gangrene of the lower extremities.

Increase of temperature, great thirst, and ravenous appetite or distaste for food, have also been remarked.

The disease is usually long-continued and not favorable for treatment, but cases do recover.

So much for the physical symptoms. A singular mental condition is coincident with the disease, which was not observed by Graves, but which Von Basedow and others have described as a desperate cheerfulness out of all proportion to the gravity of the malady. It is an extraordinary emotional state, a certain buoyancy of spirits, a hopefulness, not at all in accord with the physical status of the patient which characterizes almost every case. There is often peevishness, an unusual irascibility, and there may be at times a certain amount of depression; but the chief psychopathic symptom is high spirits. When cases are complicated with hysteria, hypochondria, or epilepsy, other mental phenomena are manifested. There may be even maniacal outbreaks. I have at hand the record of a case which came under care in a condition of dementia, but the earlier history cannot be obtained. The following, however, which has been under my observation for the past year and a half, will serve to illustrate some of the above physical and mental symptoms. I describe it especially because of the interesting psychic condition of the patient. A photograph is also presented herewith showing the degree of exophthalmia, and the size of the goitre.[1]

H. B——, female, aged twenty-one, shop-girl, single, common-school education, blue-eyed and yellow-haired, was brought under my treatment in October, 1885. Her height (5 feet 1 inch) and weight (112½ lbs.) showed the usual normal ratio between the two. She seemed in good physical health and was not anæmic, and her bodily condition is about the same now.

It was two years before this that she first noticed the beginning of the prominence of the eyes and the enlargement of the thyroid. These symptoms manifested themselves shortly after the death of her mother and some serious illness of her own, possibly typhoid fever; but these facts are related by herself, and no reliance whatever can be placed upon her statements. As bearing on the question of neuropathic taint, it may be added that her father died insane in an asylum a few years ago.

The patient's heart is somewhat hypertrophied. The number of beats per minute varies from 110 to 160. There is a loud systolic, blowing murmur heard over the heart, aorta, subclavians, carotids, and whole thyroid gland. The pulsations are visible in the larger arteries and in the epigastrium. It has been stated that the pulse in this disease varies greatly in the carotids and radials; but sphygmographic tracings in this case fail to show greater differences than exist in healthy persons. There is naturally in all persons greater accentuation in the carotids, and the tidal wave arrives there sooner than in the radial; hence the apex of the sphygmograms may often appear bifurcated. Accompanying this are two sphygmograms from the patient's carotid, taken a week apart, and also tracings from the right and left radials at four different dates. The greater accentuation in the katacrotic elevations (especially that of the tidal wave) of the carotid tracings is well marked. In all of the sphygmograms it will be seen that the blood-pressure is high.

The thyroid gland is enlarged chiefly upon the right side, and is soft and pulsating. Both eyes protrude very markedly. The exophthalmia is equal upon both sides. When the eyes are closed in sleep the lids do not cover the globes. The sensibility of the conjunctiva is normal. Accommodation is good. There is slight dilatation of the pupils, for which a little myopia will account. There are no fat-lumps under the lids, such as occasionally described. The color-vision is normal. The inco-ordination of the movements of the superior palpebra and the ocular globe, the symptom pointed out by Von Graefe and others, is entirely absent in this case. The lachrymal secretion is increased, naturally owing to the tendency to dryness of the partly uncovered cornea. The ophthalmoscope reveals vessels slightly dilated in the retina.

The patient has no muscular tremor such as described by Charcot. She has often sensation of heat of the skin. I have had her temperature taken for three weeks three times daily. Although it has varied in that time from 97½° to as high as 103° F., it was generally nearly normal in the morning, rising toward evening to 99½°, or a trifle more.

With the natural exception of the lachrymal, there has been no increase in the secretions—not in perspiration, saliva, or urine. The last-mentioned fluid has a specific gravity of 1.022, is pale, averaging 2½ pints daily in quantity, and contains no sediment, no albumen, and no sugar.

At times she has had hæmoptysis (but the lungs are normal). Nosebleed is frequent with her. She menstruates, however, never more than one day, and has had at times amenorrhœa for months.

She often suffers from thirst. Her appetite has every indication of being normal.

[1] The photograph and sphygmograms presented with the paper are here left out, because they do not differ from similar illustrations in the text-books.

There are no pathological states of the skin, such as sclerema or discoloration.

She has frequent attacks of dyspnœa, when the pulse becomes countless and palpitation extreme.

What I consider further noteworthy in this case are the enormously enlarged tonsils. These have been increased in size since about the time of the thyroid enlargement. Owing to the untruthfulness of the patient, it is impossible to decide definitely whether the hypertrophied tonsils are the result of tonsillitis or a manifestation of the same process as takes place in the thyroid gland and retro-orbital tissues. The tissue of the tonsils is of a kind very susceptible to the influence of change in blood-supply; and the tonsillar artery is part of the dilated carotid system. In the literature of the disease I find no reference made to these organs. Possibly they may never have been examined, or the hypertrophy in this patient be merely a coincidence. In any case the matter merits some investigation.

The fact that the thyroid gland is generally larger upon the right side, and that the right eye sometimes protrudes alone or earlier than the left, has led me to suggest that the cause of this may lie in the anatomical arrangement of the carotids. As the right carotid presents a somewhat more direct route from the left ventricle to the head, the shock and pressure of the column of blood are felt upon this side rather more strongly than upon the left.

The mental peculiarities of this patient had developed at the time I first saw her, and were so marked as to have her pronounced insane by her friends and physicians; and in the year and a half since then there has been no perceptible alteration in her psychic state, which may be briefly described as follows:

Subject as she is to severe attacks of dyspnœa and palpitation, when her pulse mounts to 160 and over, and her temperature rises two or three degrees, she will leave her bed in any of these spells for pleasure of any description, such as dancing, singing, or a theatrical entertainment. Effort in any useful direction wearies her, and she is indisposed to employment of even the lightest kind; whereas the nervous enjoyment she experiences in an hour's waltzing or other amusement seems to render her superior to any sense of pain or fatigue. She is utterly oblivious to the necessity of caring for herself, and will take a rôle in a play, or sing—for both of which she has a small talent—or dance a whole evening, knowing she must pay dearly for it by suffering in bed the next day. She has an unnaturally exalted opinion of herself, exhibiting to a more than usual extent the vanities of her sex as regards fine dress and a pretty appearance. She steals the dresses and finery of other women whenever an opportunity presents itself, and much watching is necessary to oppose this kleptomaniac tendency. She is constantly telling falsehoods on every conceivable subject; says she has travelled in Europe; has had this and that adventure, etc., which have no foundation in fact, and are not delusions, but which are symptoms of a degenerate moral nature. Insolence and irritability are traits which have gradually developed in her character. She will deny having stolen articles which she wears upon her person at the time of accusation.

Though naturally very plain-faced, and now unpleasantly disfigured by her protruding eyes, she believes herself very beautiful and charming. She sings and plays a little, but scarcely enough to justify her studying for the operatic or dramatic stage, for which she considers herself adapted. She manifests a fondness for male society which has been the occasion of considerable care on her account, and it is probable that she masturbates. She is also inclined to fabricate stories of gross immoralities perpetrated by those about her, her sisters, friends, or physicians, and gossip of them among her associates.

However, aside from these more marked manifestations of mental perversion, the buoyancy of spirits or emotional exaltation may be considered as very characteristic in this case.

Eulenburg mentions the frequency of alteration in the emotional state among these cases. Trousseau describes in some of his patients traits similar to many noted above.

Austin Flint, Walshe, Handfield Jones, Fletcher, and J. B. Andrews, have remarked in most of their cases irritability to some extent.

In conclusion, I would like to suggest a rather different theory of the origin of the disease from that commonly described, such as that it is due to vaso-motor paralysis, or vaso dilator irritation in conjunction with stimulation of the cardiac accelerator.

All at least are agreed that the cause is in some lesion of the nervous system. The equilibrium between the accelerating and inhibitory fibres of the heart, which hold that organ in normal rhythm and pulsation, seems in this disease to be in some manner overthrown. But I think the evidence will support rather a theory of diminished action in the cardio-inhibitory nerve than one of stimulation of the nervus accelerans cordis. That there is in most cases lessened vitality in the cardio-inhibitor is shown by the fact that veratrin and digitalis seem no longer to be able to exert much influence over the nerve. The experience of Eulenburg, Von Graefe, Fritz, Geigel, Cerf Lewy, Eichhorst, and others, is that these cardiac depressants have no stimulant effect upon the inhibitor in ordinary doses, and they do not advise the use of them. Even Trousseau, who, on the contrary, speaks highly of the efficacy of digitalis in the treatment, says that it is necessary to push the administration of the drug until toxic effects are produced. Another fact to be borne in mind is that the inhibitory branch of the vagus also regulates the rhythm of the heart, and one of the marked phases of this malady is the violent and frequent palpitation, or interruption of cardiac rhythm.

In my opinion, therefore, an anatomical lesion in the cardio-inhibitory nerve-path, or its medullary centre, which diminishes but does not destroy its functional activity, is the cause of Basedow's disease.

Because of this lesion the heart is not prevented, as it normally should be, from quickening its movements to an extraordinary degree, or from even losing at times the rhythmical character of its pulsations. Owing to the anatomical distribution of the largest arteries, and the greater directness of the route here than elsewhere, the brunt of increased blood-pressure and cardiac force is borne by the blood-vessels going to the head. After a long period of resistance these vessels tend to dilate, especially in any distensible tissue, rich in arteries and veins, that may be met with on the way. The thyroid gland is such a tissue. Indeed, the best physiologists are now inclined to the belief that the function of this organ is to regulate the blood-supply to the head. Is it strange, therefore, that long-continued cardiac acceleration and violence should tend to increase its size? Is any theory of lesion of vaso-motor or vaso-dilator nerves necessary to explain it? But there are two additional grounds for adopting this view:

1. The gland increases or diminishes in size in exophthalmic goitre with the quickening or retardation of the heart's action. The gland may be for weeks at a time only moderately distended, with a pulse at 110. Then some hours of palpitation, or some days of 160 beats per minute, will greatly augment its size.

2. As before mentioned, there is a tendency for it to enlarge first and to a greater degree upon the right side, for which the anatomical arrangement of the carotids affords to me an easy explanation.

Whether the tonsils undergo a similar change, as they might be expected to, in this disease, is uncertain, my own case being the only one recorded that would at all support such a view.

The next tissue that the blood-pressure meets to act upon is the retro-orbital, an easily distensible, elastic, cellular tissue, rich in arteries and veins. Here there is

sometimes, as mentioned before, greater proptosis upon the right side than the left, probably for the reason already given. Brain pathologists state that acute mania, which is a condition of psychic exaltation, is due to active cerebral hyperæmia; and with at least equal justice can I suggest that the mild emotional exaltation, so frequent in Basedow's disease, is probably due to the rapid and increased flow of blood to the brain, the dilatation of cerebral vessels, and pressure.

Finally, a few words as to treatment. The seat and cause of the disorder being obscure, the therapeutical measures recommended vary with the theories adopted by the different writers upon the subject. As in general with medicinal treatment, an almost laughable diversity of opinion exists as to the efficacy of certain remedies. For instance, the latest and best German authorities advise the internal use of iodide of iron, together with galvanization of the cervical sympathetic. But Troussean will tell you that both iodine and iron are very harmful in these cases.

In my patient the iodide of iron has been taken some time and galvanization of the nerves of the neck used, but thus far without benefit. An ice-bag to the cardiac region often alleviates the attacks of dyspnœa and palpitation. This treatment shall be continued until something better, more scientific, is discovered, which can only be when the mystery of the disease is solved.

STATISTICS SHOWING THE RATIO OF PATIENTS OF THE WHITE AND THE BLACK RACE WHO WERE THE SUBJECTS OF HEMORRHOIDS AND OF ANAL FISTULA, THE TWO MOST COMMON SURGICAL DISEASES OF THE RECTUM AND ANUS.

By WILLIAM BODENHAMER, A.M., M.D.,

NEW YORK.

After reading a brief report of an interesting discussion upon the subject of the "Surgical Diseases of the White and Colored Races Compared," I feel disposed to present, as a small contribution to the common stock of data upon this subject, for what they are worth, my own individual observations with regard to the two most common surgical diseases of the rectum and anus—namely, *hemorrhoids* and *anal fistula*—and the percentage in which these two affections were found in the two races according to my own experience in private practice only. It would be idle, however, to attempt to found any exact conclusions upon so small an amount of data. I hope, however, that others, feeling the same degree of interest in this matter that I do, may continue to report additional facts in relation to the surgical as well as the other diseases of the negro race, and thus aid in arriving at correct decisions upon this subject. Indeed, a complete treatise upon the nature, causes, and treatment of the diseases of the negro race in the United States would at present be a desideratum in medical literature.

In the extreme Southern portions of our country, where derangements of the liver and other digestive organs are so common, their natural concomitants, anal and rectal affections, prevail to a great extent, especially the two diseases under consideration; for it is conceded that warm climates greatly dispose to the development of those diseases. They doubtless operate by inducing the bilious constitution.

With regard to my own experience in the treatment of the Southern blacks, it was gained previous to the civil war, when they were slaves. I have but little experience in the treatment of free negroes, although I have resided in New York a number of years. In the study and in the treatment of the Southern negroes, in order to success, it was found to be both important and necessary to divide the race, as it exists, into classes—as, *blacks*, *mulattoes*, *quadroons*, and *octoroons;* for each class has its peculiarities, and differs more or less with respect to disease, to cause, and to effect, all of which had to be recognized and appreciated. In the table below, however, the negroes are classed together, as it was only contemplated in this brief article merely to compare the two races with regard to the ratio in each of the two diseases.

In examining the several volumes of my case-book, in which are recorded the date, name, age, sex, residence, occupation, disease, and the result, as related to each patient, I find that during a practice of twenty-one years in the cities of Paris, Ky., Louisville, Ky., and New Orleans, La., *ante-bellum*, I treated surgically the number of cases of hemorrhoids and of anal fistula as represented in the following statistical table, compiled from my case-book:

	Number of cases.	Whites.	Blacks.	Males.	Females.	White males.	White females.	Black males.	Black females.	Slaves.	Free blacks.
Hemorrhoids.	2,321	2,265	56	1,466	855	1,423	842	43	13	48	8
Anal fistula..	1,541	1,444	97	1,125	416	1,050	389	70	27	88	9

I will now name a few of the other diseases of the rectum and anus which came under my observation in the treatment of the Southern slaves.

I saw and treated but few cases of anal fissure in the negro, and they were principally female mulattoes.

I found prolapsus recti common among the negroes, especially among the out-door laborers or field-hands.

I saw but few cases of anal or rectal stricture in the pure negro; but I treated a number of both forms of the disease in female mulattoes and quadroons. They were mostly of a venereal origin.

I met among the negroes a number of cases of fistula in perinæo, more or less complicated with fistula in ano. They were generally caused by neglected or badly treated gonorrhœa.

I found tubercular disease of the rectum not uncommon among the negroes, especially among the cross-breeds. These cases generally proved fatal.

Cancer of the rectum, so common in the whites, must, in my opinion, be exceedingly rare in the pure negro race. So far, at least, as my own experience goes, I never saw a case of cancer of the rectum in any of its forms in a black slave, but I met with two marked cases, one a mulatto woman, fifty-five years old, and the other a quadroon woman, aged thirty-eight.

As to the congenital malformations of the rectum and anus, they were very uncommon among the Southern slaves. So far as my experience extended, I only met with one case, and that was at New Orleans in the winter of 1848. It was a male mulatto child. The case is reported in my treatise on the congenital defects of the rectum and anus.

The status of the Southern negroes is now completely changed, consequently their habits, their customs, and their diseases must also necessarily have undergone changes with it, so that the treatment of their diseases now, as free, must also differ, more or less, from that consequent upon their former condition as slaves.

In their state of servitude, especially as out-door laborers or field-hands, the slaves were compelled to lead regular lives; they were drilled and disciplined like soldiers, having stated times for meals, for work, for rest, and for sleep, and, as a general rule, they always had plenty of food, plenty of clothing, and plenty of work, all of which was certainly of benefit to them, so far as their health was concerned. When they became sick or injured they were at once sent to the plantation-hospital, where the same physician or surgeon who attended the whites attended them.

It was supposed by those who were unacquainted with the real condition of the Southern slaves that they were necessarily oppressed, but their very appearance was a contradiction of this. Their bodies, instead of being

emaciated or attenuated, were plump, full, and round, and their skin, instead of being dry, husky, and scaly, was soft, oleaginous, and glossy; and as a further evidence, generally, of their sound and their physically good condition, they multiplied like rabbits. They were docile, tractable, cheerful, and happy, and had no cares for the morrow; and at the close of the day, when their work was done, they would lay down "the shovel, the rake, and the hoe," and retire to their cabins "to take up the banjo, the fiddle and bow." Indeed, their station in life in the South as slaves really saved them from many of the habits, customs, callings, and diseases of civilized life, and was to them a real blessing in their then condition. I do not mean by this language, however, to be understood as endorsing the system of slavery, but simply to show the favorable hygienic or sanitary condition of the negroes under that institution; for it must be perceived at once that the question of slavery, either right or wrong, is not involved in this purely medical discussion.

Previous to the abolition of slavery in the South, an impression prevailed generally in the North that, in consequence of the depressing and evil effects, as was supposed, of that institution, the slaves suffered greatly in excess of the whites from diseases generally, and that the mortality was always great. Statistics proved, however, that that impression or belief was by no means warranted; but, on the contrary, there was much less disease among the slaves, according to numbers, than among the white inhabitants.

The diseases of the slaves, as a general rule, were quite amenable to proper treatment, and during illness they were not, generally, fretful or complaining, but manifested much patience and calmness; and it was well known by surgeons that they bore injuries and surgical operations equally as well as the whites, and recovered as rapidly.

249 Madison Avenue, June 22, 1887.

SPECIMEN OF PYO-SALPINX REMOVED DURING THE ACUTE STAGE OF SYPHILIS.[1]

By A. J. BOLDT, M.D.,
NEW YORK.

A. A——, aged twenty-two, married three years; never pregnant. Menstruation began at seventeen years. Four years ago the patient first began to complain of vague pelvic pains, but avers that up to the present time she received no treatment, and that only within the past two months she has been suffering severely. The menses have always been irregular and scanty, the flow occasionally not oftener than once in two or three months, and usually only of one day duration; but she suffers intensely with dysmenorrhœa, the pain beginning one to two days prior to, and continuing during the flow. Now she complains of constant severe pain in the left inguinal region, and of intense backache in the lumbar region, which is also persistent. Some pain in the right inguinal region, but neither so excruciating nor constant as on the opposite side. These pains are so severe that the patient is unable to attend to her domestic duties. Severe cephalalgia, pains radiating down the thighs, and occasional chills are also present. She positively denies having had illegal intercourse with anyone, until three and a half months ago, and also denies any single symptom of gonorrhœa. She informed me recently that she elicited that her companion had a chancre at the time of intercourse with her, but denies more. Her husband denies having had venereal disease at any time. Dr. S. Kohn, who referred her to me, was then treating her for syphilitic pharyn- and laryngitis; she also had a well-marked lenticular papular syphilide, and the characteristic mucous patches of syphilis on the mucous membrane of the mouth and on the tongue.

[1] Remarks made before the Surgical Section of the New York Academy of Medicine, with the presentation of the specimen.

On examination both tubes and ovaries could be felt much enlarged and tender to touch. The right adnexa could be felt much enlarged and movable; not so the left, which seemed to be surrounded by a mass of exudate, and was only distinctly mapped out under anæsthesia. The temperature at this time was 99.2° F. in the axilla, and it may be mentioned that her temperature, under constant observation during the next few days, varied between 99° F. and 100.6° F. in the axilla.

The diagnosis of a probable double pyo-salpingitis of syphilitic origin was made, and, on account of the severe and constant pain from which the patient was suffering, abdominal section for the removal of the diseased uterine appendages *without much delay* was advised by me, because the tubes seemed to me apparently distended to such an extent that the probabilities were that the walls at some point were so much thinned that there was some danger of rupture, and subsequent general peritonitis, which is almost positively fatal in its result when due to such a cause.

The patient having consented to operation, this was done in the usual way, and presented nothing unusual, except on the left side, where the adhesions were quite firm, as was suspected by me. The wound healed by first intention, and there was not the slightest sign of pus, to be seen anywhere. This is the second time that I have opened the abdomen during the acute stage of syphilis, with an equally good result in both instances, so that I believe the only danger attending operations during the acute stage of this constitutional disease is self-infection, therefore the operator need be careful to prevent this on himself by the usual precautions; but so far as the healing of the wound is concerned, I do not believe the constitutional disease makes a particle of difference. Of course the case stands differently if the constitution has become broken down by the chronicity of the ailment, as in tertiary syphilis.

I do not wish to affirm with positiveness that *this* pyo-salpinx is due to syphilis, but it is my opinion that such is the case, and that we have before us a variety of disease called syphilitic pyo-salpingitis, on the basis of its etiological factor, for the following reasons:

First, the patient's condition became worse soon after the time of infection with the syphilitic poison, and we know from clinical observation that an inflammation of the Fallopian tubes, with the formation of pus within them, may result very rapidly after exposure to some suitable cause, especially if there had previously been present a *catarrhal salpingitis*, to which the history of this case points.

Secondly, because an examination of some of the pus did not reveal the gonococci of Neisser, although this in itself would be no proof against the specimen which I exhibit, being of the variety known as *salpingitis gonorrhoica*, for the reason that occasionally the gonococcus cannot be found in the tubal secretion of cases about which there is no doubt as to their gonorrhœal origin from a clinical stand-point. Occasionally we meet cases in which a salpingitis is developed within twenty-four hours, from an injudicious intra-uterine application; that is, the symptoms of an inflammation of the uterus, parametritis, and a localized peritonitis are present; then, after the acute symptoms have passed off, the enlarged Fallopian tube, or tubes, with the usually co-existing oöphoritis, frequently more or less parametritis, etc., can be recognized by the experienced examiner.

To prove this by actual observation on the dead body has been my good fortune within the past few weeks.

I was called to see a patient, in consultation with a gentleman, who gave me the following history: The woman had for some time been suffering from chronic endometritis, for which she had been under my colleague's care. He had been in the habit of using intra-uterine injections of tincture of iodine, full strength, and so far without any serious effect; twelve days previous to the time when I saw her with him, she received the last

treatment of this kind, and at once began to complain of intense cramps in the lower part of the abdomen, so severe that she rolled on the floor in his office. Morphia was used hypodermically, so that in about two hours the pains had abated to such an extent that the patient could go home, or, rather, be taken home. On the next day the symptoms of a localized peritonitis were fully developed, and also of rheumatism, to which she had been subject for several years, and which had left its effects on the heart. The pains in the lower part of the abdomen were constant and severe, which, in addition to the rheumatism from which she was suffering, made it necessary for her attendant to keep her under morphia.

The temperature had been between 102° F. and 104° F. in the vagina; at the time of my visit, however, it was 105.6° F. On examination I found the uterus very sensitive, and to the right side of this organ the pelvis was filled with an exudation; so sensitive, however, were the parts that I desisted from a more careful examination without an anæsthetic, the use of which was not deemed advisable by either of us on account of her very low condition, in connection with the existing acute endocarditis, which had been ingrafted upon the chronic endocardial inflammation. I interpreted the case as follows: The iodine had found its way through the uterine opening of the right Fallopian tube, and into the tube, which caused the severe pain of which she at once began to complain. The fact that she apparently complained of equally intense pain on the other side was not taken into consideration by me—that some iodine had entered both tubes. That the fluid had penetrated into the tube on the right side I concluded from the fact that only on one side the exudation was present. The diagnosis then rested on a chronic endometritis primarily, the treatment of which, by an unfortunate accident, gave rise to a traumatic salpingitis, which rapidly became septic; in other words, it became what is practically known as a pyo-salpinx, which, however, could not be distinctly felt by me, for the reasons already given, but was strongly surmised from the history, and the fact of feeling such exudation on one side, which the doctor said had not been there previously.

The salpingitis also gave rise to the parametritis dextra and the pelveo-peritonitis, etc.

That her endocarditis had a septic element, in all probability an ulceration-endocarditis, from this cause, was no further question in my mind.

The patient died on the following day, and the autopsy confirmed my suspicion. The right Fallopian tube was distended with pus and the corresponding ovary had several minute abscesses on the surface and in the interior, besides being much enlarged; the tube ruptured while attempting to remove it from its bed of adhesions, and it was believed that, on account of its very thin walls, in all probability this accident would have taken place later spontaneously, if the patient had not succumbed to her endocarditis. The left tube showed evidence of *catarrhal salpingitis* only. This case, then, serves as a good illustration of how rapidly a pyo-salpinx will sometimes develop. I could also cite a case which occurred during the earlier part of my own practice, from an exactly similar cause, the actual condition of which only became clear to me later; the patient recovered, but the accident taught me a never-to-be-forgotten lesson, and how to make intra-uterine applications in a more careful manner. I might go on and give examples of three other cases of rapid development of pyo-salpingitis, were it necessary. A factor which I think should be taken in consideration when a *pyo-salpingitis* does develop so rapidly is, that previously a *catarrhal* salpingitis, which in all probability was never recognized, had existed in many, if not in all, instances, which makes the ground, so to say, quite fertile. The term *pyo-salpingitis*, without another adjective, is perhaps quite sufficient for all practical or clinical purposes, but, scientifically, it is exceedingly improper, because it expresses absolutely nothing more than an inflammation of the Fallopian tubes, which, as a result of this inflammation, are filled with pus.

I would urge very strongly, therefore, that all become accustomed, in giving a description of any particular case for scientific purposes, to bear in mind the different etiological factors, and then specify the pyo-salpinx accordingly, if the cause can be ascertained; if in doubt, to avail ourselves of the advances made in bacteriology, which will, if the examinations be made by competent observers, clear up some cases, and undoubtedly in the future give us more advantages. Such accumulated specification and observation of cases with reports will, perhaps, later on lay the foundation for different views regarding this disease.

Any variety of the disease may, I believe, result in death—for instance, I have seen a general peritonitis in a phthisical subject, which was caused by a pelvic abscess, which again was caused by the rupture of a *pyo-salpinx* on the left side. The ovary appeared to me, macroscopically, tuberculous, which a microscopical examination confirmed, and proved the salpingitis to be of that variety properly designated as tubercular salpingitis. It is not at all my intention to go into the different varieties of salpingitis, leaving this for some future occasion; my object merely being to attempt to show that a well-marked *pyo-salpingitis* may be produced by syphilitic infection, and that occasionally, in a comparatively short space of time, as I believe this to be in my case, and also that, on account of existing acute syphilis, we need not hesitate to do even a capital operation for fear of the wound not healing readily; only must we bear in mind the one great secret of successful surgery—*strict asepsis.*

A CASE OF WELLNIGH FATAL HEMORRHAGE FROM THE CONJUNCTIVÆ,

The Result of an Instillation of a Two Per Cent. Solution of Nitrate of Silver in a Day-old Infant as a Prophylactic Measure.

By OREN D. POMEROY, M.D.,

NEW YORK.

B. A——, a male child, from the middle walks of life, was born of healthy parents on April 30, 1887. The physician did not arrive until after the child was born. Mother had excessive uterine hemorrhage, which reduced her to an almost pulseless condition, and the most prompt measures were required to restore her. She, however, made a rapid recovery.

On account of the mother's requiring so much attention the child's eyes were not specially attended to until the next day, at about 12 M., when two drops of a two per cent. solution of arg. nit. in water were placed upon the slightly separated eyelids. The doctor thinks that not more than one drop came in contact with the palpebral conjunctivæ; this was at once neutralized with a solution of salt and water. The drops were applied from a spoon, and no laceration of the conjunctivæ resulted from opening the lids.

At once the most violent pain resulted, which continued for five or six hours, the child crying constantly during this time.

At about 7 or 8 P.M. a serous discharge was then noticed from the eyes, which in two or three hours became tinged with blood.

This continued as a slow oozing during the night, becoming more sanguinolent until about ten o'clock of the next day, when the doctor arrived. He found it to be now almost wholly sanguinolent. He at once used cold applications which, having no effect, were changed to hot. Neither of these succeeding, resort was had to digital compression. This arrested the hemorrhage dur-

ing the contact of the fingers, but as soon as the fingers were removed bleeding recommenced.

I arrived at 1 P.M. Compresses of absorbent cotton, with vaseline to prevent imbibition, were at once applied by means of a firmly applied bandage; this arrested the hemorrhage for an hour, but it again returned, first in one, and after a little in the other, when two more bandages were applied over the first. This controlled the hemorrhage until 6 P.M., when it again commenced. At 8 P.M. I again saw the patient, and found the bandage soaked with nearly or quite pure blood, clots readily forming beneath the eyelids.

Iced applications were now made with temporary success; this failing after an hour or an hour and a half, the upper lids were everted and touched with alum in substance. This did no good; the slow but persistent oozing of blood was startling to observe.

A compress was then applied very firmly, with sheet-rubber applied to the eyelids, knowing that blood *could not* soak into the cotton compresses. The bandage was applied very tightly indeed, the attending obstetrician reminding me that a child's head in the inferior straits was often compressed for hours with great intensity without harm. The bleeding now ceased.

This compress remained thirty-six hours; on removing it, it was found that the left had not bled a particle, but the right had lost about half a drachm.

The bandage was reapplied to the right for one day, when there was found to be no more hemorrhage. Blood-clots were found beneath each eyelid, but it was thought injudicious to remove them, and a bichloride collyrium was used.

On the next day the clots were found to have disappeared, and a saturated solution of boric acid in water was ordered to be used twice a day.

The lids were now carefully inspected, and each upper lid showed that there had been a superficial slough. The retro-tarsal folds were considerably swollen, but the corneæ were perfect. Child opened the eyes readily; no photophobia; continued wash.

At the third day it seemed as though the child might die. The pulse was very feeble; patient extremely quiet; respiration weak; showed inability to nurse, for hours at a time, and when it did so only caught the nipple feebly. It was estimated that four ounces of blood had been lost. Stimulants were used, and in two days the child rallied satisfactorily, so that in a week there was no further trouble. The parents seem fairly healthy and strong; the mother, it is true, had serious post-partum hemorrhage, but there was no tendency toward being hæmaphyllic, nor is there a history of anything of the kind in the family. The child only bled from the conjunctivæ.

I found it difficult for a time to believe that the collyrium could be the cause of the trouble; not more than a single drop touched the palpebral conjunctivæ, not a particle touched the globes on account of somewhat imperfect separation of the eyelids, and the prompt neutralization of the collyria by a solution of sod. chlorid. still further rendered the application apparently safe. Three weeks after the instillation both upper eyelids exhibited a minute cicatrix.

I have made ineffectual efforts to obtain an exact examination of the solution, to determine whether it was properly dispensed. By the chloride-of-sodium solution I thought a more dense precipitate was thrown down than in the case of a solution known to be two per cent. It evidently was not *much* stronger than intended.

MEDICINE AMONG THE BEDOUINS.—The Sultan of Turkey has sent a commission to Tripoli to study the various methods of treatment of disease in vogue among the Bedouins, and the different plants used by them for therapeutic purposes.

NOTES ON TWO CASES OF POTT'S DISEASE, ILLUSTRATING THE DIFFICULTY OF DIAGNOSTICATING BETWEEN UPPER DORSAL AND LOWER CERVICAL CARIES IN VERY YOUNG CHILDREN.[1]

BY JOHN RIDLON, A.M., M.D.,

ATTENDING SURGEON, FIRST ORTHOPÆDIC DIVISION, DEPARTMENT FOR THE OUT DOOR POOR, BELLEVUE HOSPITAL, NEW YORK.

I DESIRE to present to you notes on two cases of Pott's disease. They are as follows:

CASE I.—Male, born of healthy parents, and with hereditary history free from tuberculosis, scrofula, or syphilis, so far as can be ascertained. When six months old he began to throw his head backward and show evidence of pain when the head was moved. This condition increased until, after four and a half months, the head rested on the shoulders and could not be bent forward from that position. Lateral bending in either direction was also equally resisted; and there was but slight rotation. The chin looked forward and upward, and the sterno-mastoid muscles were equally prominent. Any attempted movement of the head caused screams of pain, and the mother was constrained to nurse him on her knees by the cradle. There was no evidence of kyphos at any point. The finger was not passed into the throat. He started and cried in his sleep, and had grown thin.

CASE II.—Male, has a good hereditary history so far as can be learned, with the exception that one grandmother had "consumption." The child was healthy up to the ninth month. After that he had a cough and was sickly; when twenty-eight months old he began to throw his head backward and show stiffness in the neck. There was little or no complaint of pain, but there was restlessness in sleep. He was a fat, but flabby, child. At the end of eight months he walked with head thrown well back, almost resting on the shoulders; chin looking forward and upward; sterno-mastoid muscles equally prominent, and no facial evidence of pain. The head can be bent backward to the normal; bent to either side somewhat, but cannot be bent forward; on attempting the latter he cries with pain. There is slight possible rotation. He eats and sleeps well, and shows no evidence of pain when left to himself. There is no evidence of kyphos anywhere.

Now, to what condition did these symptoms point? That there was spinal caries there could be no doubt. The position of the head, thrown far back, its weight supported by the elevated shoulders; the muscular rigidity limiting forward bending, but permitting backward and, to some degree, lateral bending and rotation, and the equally contracted sterno-mastoid muscles pointing the chin directly forward, taken in connection with the absence of pain about the chest and epigastrium; the absence of paraplegia, and of kyphos after, in the first case four, and in the second eight, months without treatment, led me to locate the caries in the lower cervical vertebræ.

The progress, however, showed the error of my conclusions, and this is my excuse for presenting these cases. The treatment in both was the same. They were put in bed, on their backs, and traction was made by means of a sling about the head and pulley and one-pound weight. In the first case, the ten-months-old baby, at the end of three days the pain was greatly relieved; he slept quietly, and the position and motions were greatly improved. After five months the head was in normal position, and could be freely moved when resting on the pillow; but the patient could not sit up and could not move his legs. The tendon reflexes in the lower extremities were increased, and there was found to be a sharp, angular kyphos, involving the first, second, and third dorsal vertebræ. In the second case, after three months the head

[1] Read before the American Orthopædic Association, June 16, 1887.

was in normal position and could be moved freely when resting on the pillow. The patient could sit up and hold the head in normal position for a short time, and there was no evidence of pain except when the head was bent forward with some force. Four months later, the case having progressed favorably as to the neck-symptoms, the tendon reflexes of the lower extremities became exaggerated, and an examination of the dorsal spine revealed a kyphos involving second, third, and fourth dorsal vertebræ.

The lesson taught me by these cases is this: That in *very young* children, caries of the upper three or four dorsal vertebræ may give symptoms referable only to the neck, and should lead us to exercise great caution in diagnosis when the symptoms point to disease in the lower cervical region.

322 West Fifty-seventh Street.

Progress of Medical Science.

Treatment of Dropsy by Permanent Baths.—In the course of a paper upon the use of permanent baths (at a temperature of about 95° F.), L. Riess, after giving instances of their value in cases of spinal disease and injury, adduces some rather remarkable facts of their efficacy in the treatment of dropsy, whether cardiac or renal. These cases are often complicated with bedsores, erysipelas, and gangrene, for which such treatment would be suitable, but he says that he long withheld it because of the idea that cardiac or pulmonary disease would be a contra-indication to its employment. However, in 1879, in a case of extreme cardiac dropsy (mitral and aortic disease) with considerable erysipelas and cutaneous gangrene of the legs, he determined to try the effect of the permanent bath as a last resort, not without some misgiving lest the immersion should increase the dyspnœa and dropsy. The result proved quite the reverse, for a rapid improvement took place, and when, after having been in the bath a fortnight, the patient returned to bed, the dropsy and other severe symptoms had disappeared. Since then Riess has adopted the procedure in a large number of dropsical cases, and invariably with benefit, the dropsy in most cases (whether renal or cardiac) diminishing within the first forty-eight hours in a striking degree. The quantity of urine is not increased *pari passu*, so that it is suggested that the effect of the permanent bath is to increase the functional activity of the skin, which is contrary to the prevalent notion. The good results obtained in cases of chronic rheumatism so treated are also mentioned, and it is held that the application of the method is practically very simple, it being necessary, of course, to allow the patient to lie comfortably suspended in a hammock, and to place a thick woollen covering over the bath to retain heat as much as possible. At first it is well to allow the patient to leave the bath at night, but as he gets more used to it he may spend days and nights in it with much comfort both to himself and his attendants.—*The Lancet*, July 23, 1887.

Reformation of the Aqueous Humor after Paracentesis.—Deutschmann, experimenting on the dead subject, found that if the aqueous were evacuated, it was replaced by a fluid which was richer in albumen than the aqueous, and more resembled the vitreous; from this he concluded that in the living subject also the aqueous was replaced to a great extent at the expense of the vitreous (*London Medical Record*). The author, however, points out that the conditions in the dead and the living subject are very dissimilar, and that one cannot argue from one to the other. The experiments of Ehrlich, Schöler, Uhthoff, and Schick with fluorescence on the living subject are inconclusive and contradictory. The writer has therefore endeavored to solve the question by further experiments. In these, iodide of potassium was introduced into the circulation in rabbits by subcutaneous injection; this appeared in the aqueous and lachrymal secretion ten minutes later, but not in the vitreous till twenty or thirty minutes; it possessed, moreover, the additional advantage that its presence could be readily detected by means of the reaction with starch. An incision was made in the right anterior chamber, the subcutaneous injection was then made, and the corneal wound repeatedly reopened until the iodine appeared in the aqueous; it was then allowed to close, and the chamber became restored twenty minutes later. The animal was then killed; both eyes were enucleated and placed in a freezing mixture. As soon as they were hardened, a vertical transverse section was made behind the lens, the latter removed; the frozen aqueous was then removed *en masse* and examined. Less iodine was always found in the aqueous of the punctured eye. Had the aqueous been reformed from the vessels of the iris or ciliary processes, the reverse would have been the case, since in the eye not operated on, the newly secreted aqueous would have been diluted with the original non-iodized aqueous. Since, however, the iodine had not had time to reach the vitreous, the result was consistent with this being the source from which the chamber was refilled. In a second series of experiments the aqueous was not evacuated till two hours after the subcutaneous injection of the iodide, so that there was ample time for the vitreous to become impregnated. The result was the converse of that obtained in the former experiments, the anterior chamber of the eye operated on now containing the most iodine. In order to eliminate any effect from the lowering of the intra-ocular tension, an equal quantity of fluid was removed from the vitreous in the other eye, but the result was the same. From these experiments the writer concludes that the reformation of aqueous humor takes place chiefly from the vitreous by filtration through the suspensory ligament, and that the amount secreted by the ciliary processes and iris is comparatively insignificant. These conclusions can only be held to be proved as regards the resecretion of aqueous after its evacuation, and not as to its formation under normal conditions.

Chronic Laryngitis and its Sequelæ.—In the *Edinburgh Medical Journal* Dr. Hunter Mackenzie publishes a lecture on chronic laryngitis and its sequelæ. Simple chronic laryngitis and thickening of the laryngeal structures may occur as a consequence of acute laryngitis, or from repeated attacks of the subacute variety: occasionally its mode of development is protracted and insidious. It may be partial—that is, only one-half of the larynx may be thickened permanently—it may be general, affecting more or less all the intrinsic structures. The question of degree or locality of the inflammation bears an important relation to prognosis. Chronic laryngitis may be primary or consecutive. Primary chronic laryngitis indicates that the laryngeal affection has not been preceded by any local or general affection; the term consecutive may be applied to that variety which precedes or supervenes during or after the course of the zymotic diseases, malignant disease, or pulmonary phthisis, or which is the result of extension from the nares or pharynx. In simple chronic laryngitis there is very seldom any true ulceration or loss of substance, unless there is evidence of struma, tuberculosis, or syphilis. The character of the voice almost entirely depends upon the amount or degree of structural alteration undergone by the vocal cords. Complete aphonia (whispering voice) is, in the absence of nervous or mental causes, indicative of severe laryngeal changes, and shows destruction of the vocal cords, or of the cords and ventricular bands; it is a point to be remembered that a fairly effective voice can be produced by the ventricular bands, should the vocal cords be destroyed. Chronic laryngitis, in addition to the symptoms produced on the voice, respiration, cough, etc., may sometimes be the cause of gastric disorders; when pharyngitis is present, and the saliva is in

excess, or when frequent movements of swallowing are made, owing to the sense of tickling at the back of the throat, an excessive amount of air is swallowed, giving rise to gastric flatulence. The following are some of the sequelæ of chronic laryngitis. In the insidious form, the possibility of tubercular degeneration is always present; in these cases it is only by the examination of the sputum or laryngeal secretion, and the presence of the bacilli of tubercle being detected, that one can be certain the case is one of tubercular disease. Another sequela of chronic laryngitis is the formation of new-growths; these may be papillomatous, mucous, fibrous, or cartilaginous, according to their seat of origin. The more chronic a case is, the more likely is the supervention of the most serious of all sequelæ, the tubercular degeneration. In the case of malignant disease of the larynx no definite conclusion should be arrived at without examining microscopically the sputum or pieces of the growth, as in its early stages, and even in its later stages, malignant disease possesses no distinguishing characters to the naked eye. With regard to the treatment, it must be essentially of a local character to be of any use, by means of inhalations, sprays, powders, or pigments. In well-marked cases recourse should be had at once to pigments, and of these nitrate of silver is the best. Commencing with a solution of thirty grains to the ounce, the strength should be gradually increased every ten to fourteen days, until one hundred and twenty grains to the ounce or even more are used. These pigments ought to be applied locally by means of a laryngeal brush, under the guidance of the laryngoscope, at first three times and afterward twice a week, over a period of several months; this energetic treatment is necessary only in well-marked cases of thickened vocal cords, or of the intra-laryngeal mucous membrane. In the chronic laryngitis dependent upon chronic nasal catarrh, attention should be directed to the nose; the nasal passages ought to be frequently cleansed by means of a solvent spray (one drachm of bicarbonate of soda to a pint of water), and immediately after an astringent solution ought to be applied, such as sulphate of zinc or acetate of lead, one or two grains to the ounce of water. At the same time the pharynx should be occasionally stimulated by the application of a solution of chloride of zinc, twenty or thirty grains to the ounce. In granular pharyngitis the application of London paste, or of the galvano-cautery, to the prominent follicles is usually necessary. When chronic laryngitis has ended in the formation of distinct growths, they must be removed either by intra- or extra-laryngeal surgical measures. Certain of the sequelæ of chronic laryngitis may necessitate the opening of the windpipe, and the operation of tracheotomy is to be preferred to thyrotomy, if the same objects can be obtained by it. The rest and freedom from irritation that is obtained after tracheotomy often cures a chronic laryngitis which may have become serious, and in cases of tubercular disease much comfort can often be given to the patient by the early performance of this operation. The author concludes his lecture by urging on all medical men the importance of treating cases of chronic laryngitis with promptness in the early stages, so many cases being neglected at first, when some active measures might be taken, which become useless if deferred.

Diseases Resulting from Wine-tasting.—Inquiries have been made whether the profession of wine-tasting is habitually followed by symptoms such as affect tea-tasters. In the *Annales Médico-Psychologiques* there are two papers on the effect of this professional intoxication in the cities of Bordeaux and Dijon. The first of these papers is by Dr. Donnet, physician of the asylum at Bordeaux, which is the great emporium for the wines of the Garonne and Dordogne. In this city the trade of wine-taster or *dégustateur* is very common. These men are not infrequently troubled by affections of the head and stomach similar to what is suffered by drunkards. They are not obliged to swallow the wine which they taste; very often they spit it out and sometimes wash the mouth. Dr. Donnet gives instances in which the health became deranged even when they never swallowed the liquor which they tasted. In one observation a young man of thirty-two used to taste from thirty to forty barrels of wine every day, and now and then brandy and rum. He never swallowed any. After two years of this occupation he became very irritable, lost his appetite, slept ill, and had illusions of general sensibility, with pain in the chest, and feelings of faintness and suffocation. On giving up wine-tasting he at once began to improve, and his natural placidity of temper returned, though he was still subject to nervous weakness, as shown by being easily moved to sadness and tears. Dr. Donnet tells us that a great deal of wine is drunk in Bordeaux. Rich people pride themselves on their taste in wines, and men in good positions are frequently met with who drink a litre and a half at every meal. On this account disorders of the circulation, stomach, liver, or kidneys, are common, and statistics prove that there are more deaths from apoplexy in Bordeaux than in any town in the world. Dr. E. Marandon de Montyel, the physician-superintendent of the asylum at Dijon, has studied the symptoms on the wine-tasters of Burgundy. The result of these inquiries tends to show, that unless the wine-tasters swallow some of the liquor, no intoxicating effects are produced. In tasting red wines it is not necessary to swallow, but to appreciate the flavor of white effervescing wines one must swallow a little. He observes that tea-tasters always swallow some of the tea, which explains the nervous symptoms from which they suffer.—*London Medical Record.*

Manipulation of the Kidney as a Means of Dislodging Renal Calculus.—An ingenious method of dislodging an impacted calculus in the kidney has been reported in *The Lancet*, by Dr. W. H. Bennett, of London. The patient, a woman, was quite thin, and the kidney could be felt through the abdominal parietes. Manipulation of the organ was proposed, with a view of bringing about the passage of the calculus down the ureter. To insure complete relaxation the administration of an anæsthetic was proposed, but was rejected by the patient. The patient was then laid upon a couch, the fingers of the operator's left hand were dipped deeply into the abdominal wall over the kidney, while his right hand was pressed forward into the loin. The kidney was easily felt between the two hands, and was kneaded as thoroughly as circumstances would admit. The manipulation caused much aching and tenderness, but the patient was well enough to walk away afterward. Two days after the manipulation the patient reported that she had suffered much discomfort for the rest of the day after the manipulation, and that she was siezed as she was going to bed with a most acute pain in the affected loin and side of the abdomen. The pain lasted for about half an hour, during which she vomited twice. All at once an uncontrollable desire to micturate occurred, and the pain immediately disappeared. No further pain followed. Dr. Bennett is of the opinion that a small calculus was dislodged and made its way down the ureter, although no evidence of its having passed *per urethram* was forthcoming. He suggests that manipulation without incision will prove of utility in certain cases of renal calculus not too far advanced, and offers the above case as corroborative of this opinion.

Pyorrhœa Alveolaris.—Dr. Pedley read a paper at the Odontological Society upon the above subject (*The Lancet*). Pyorrhœa alveolaris is characterized by conditions as follows: The mucous membrane, especially that adjacent to the teeth, is deeply congested, tumid, and thickened, and detached from the necks of the teeth and from the roots. A thick, fetid discharge may often be pressed up between the teeth and mucous membrane, which gives to the breath a very repulsive odor. Later, the alveoli become absorbed, and at times more or less

denuded, while the fangs of the teeth become coated with a layer of thin, hard, green-brown tartar. Ultimately, the disease progressing, the teeth, one after another, drop out. The pathological changes which take place are hypertrophy of the muco-periosteal fold around the teeth, accompanied by dilatation of capillary loops, enlargement of the papillæ, and rapid proliferation of epithelial cells. Later the gum becomes firm and contracted, and displays increase of fibrous tissue. The changes which go on in the socket have not been yet satisfactorily worked out, but the examination of the jaws of some carnivora which were apparently affected with pyorrhœa alveolaris would lead to the supposition that there is ostitis of the alveolar process spreading toward the apex of the socket. There are many differences of opinion as to the causes; some maintaining that it is of parasitic origin aud due to a specific bacillus, but there is no good proof of this; others that it is catarrhal, and an extension of inflammation of the mucous membrane; others that it is due to the irritation of small deposits of hard tartar under the edge of the gum, but this is plainly not the case, for the disease may be far in advance of the deposit, and in some cases there is not any to be found. It is probably due to some constitutional condition, and the fact that it is often symmetrical, and frequently hereditary, gives support to this view. It occurs in the mouths of patients whose health has been undermined by debilitating influences and injudicious habits of living; it is a common sequel of malarial fever in America; young persons recovering from eruptive fevers are sometimes subjects of pyorrhœa alveolaris; and frequent pregnancies are a fruitful source of the disorder. Attention has been lately drawn to the shedding of the teeth in tabes dorsalis, but it does not by any means seem to be a constant symptom. Mr. Bland Sutton has found that premature loss of the teeth is a very common feature in cases of rheumatoid arthritis in animals, and has also met with it in mollities ossium and other wasting diseases. Magitot, who views the alveolar-dental periosteum as a ligament, and not of the same nature as osseous periosteum, calls the disease symptomatic alveolo-arthritis, and mentions especially as causes chronic Bright's disease and glycosuria, in which latter, he says, the phenomenon is absolutely constant.

The Treatment of Lupus by Injections of Corrosive Sublimate.—Dr. Tansini narrates the treatment of a case of lupus of the nose and face by means of repeated injections of corrosive sublimate. He began with a weak solution, corrosive sublimate 1 to 200. This produced no reaction of any kind. A stronger solution, 1 to 100 was then used. This produced some tumefaction and œdema in the neighborhood of the punctures, and slight suppuration in some of them. Some fourteen or fifteen injections of a few drops were practised. Improvement soon became marked, and eventually all traces of the disease disappeared, the only marks left being those of the punctures in which suppuration had taken place. Dr. Tansini was led to try these injections by the following considerations: 1, That lupus is a form of tubercle; 2. that the bacilli are few and have no tendency to diffuse themselves; 3, that corrosive sublimate, has proved certainly destructive to bacilli. He claims advantages for this method on account of lessened pain and disturbance and superior cosmetic results.—*Gaz. degli Osp.*

Carbolate of Mercury in Syphilis.—Dr. Shadek, of Kieff, being anxious to try the effects of carbolate of mercury, which has been strongly recommended in syphilis by Professor Gamberini, requested M. H. Brandt, a pharmacist in Kieff, to prepare some for clinical use. This he did by precipitating a very dilute solution of bichloride of mercury with a concentrated alcoholic solution of carbolate of potassium. A yellowish precipitate was obtained, which, after being frequently agitated with the liquid for twenty-four hours, assumed a whitish appearance. It was filtered and washed with distilled water till the washings showed no traces of chloride. It was then transferred to a fresh filter-paper and dried under a bell-jar. In this way a nearly white tasteless amorphous substance was obtained, which was scarcely acted upon or dissolved by cold, but was readily soluble in boiling, hydrochloric acid. The name given to it by Dr. Shadek is "hydrargyrum carbolicum oxydatum," and he has been using it in his private practice for several months. At first he gave it in the form of pills, one of which, containing about an eighth of a grain, was ordered three, or occasionally four, times a day. It was well borne, and did not interfere with the digestion. In some cases the treatment was continued for six or eight weeks, without producing colic or other disagreeable symptoms. The total number of syphilitic cases in which it was given internally was thirty-five (twenty-six men, six women, and three young children). In five of these there was swelling of the gums and salivation. Mercury was found in the urine after the third dose. Its therapeutic value was especially remarkable in macular and tubercular syphilides and in syphilitic psoriasis of the palm and the sole. Syphilitic rash and slight relapsing forms yielded to the treatment in from two to four weeks; in syphilitic affections of the mucous membrane, and in papular and pustular eruptions, from four to six weeks were required. Multiple enlargements of glands were but little affected by it. In the case of children of from two to four years old, doses of about the fifteenth of a grain were well borne twice daily.—*The Lancet.*

Cancer of the Bronchial Glands and Lung.—From a study of this subject, published in *The Lancet* July 9, 1887, Dr. Boyd concludes: That primary cancer of the thorax is of not unfrequent occurrence, generally appearing in hard drinkers, and the symptoms of it are developed apparently after catching cold. That it is to be found in two situations within the thorax—namely, the bronchial glands and the anterior mediastinum; and is of the mixed variety, scirrhous and encephaloid. That persistent blood-spitting is a very usual symptom in its growth, and indicates infiltration of the lung and pressure on the bronchial veins; and that the so-called characteristic red-currant-jelly expectoration is a rare symptom. That fixed pain in the thorax is not always present, and when it is, it is more usual in the mediastinal form of the disease. That the disease is generally accompanied by aphonia and congestion of the larynx in its early stages, and by paralysis of one or other of the vocal cords in a later stage. That when in the bronchial glands it is invariably accompanied by symptoms of pressure on either one or other of the bronchi, or on the œsophagus, causing symptoms of stricture. That pleural effusion containing blood is very frequent on the side affected, and in its growth forward from the root of the lung it involves the pericardium, and causes pressure on the superior cava or pulmonary veins. That when in the bronchial glands its later stages may simulate advanced phthisis very closely. That it may be occasionally distinguished from phthisis by its pressure symptoms on the bronchi, its dulness being more central and more extensive, with absence of crepitus and more urgent dyspnœa, while no bacilli are found in the expectoration. That malignant intra-thoracic disease is generally fatal in from two months to six, though Dr. Walshe gives the average duration as from three months to thirteen.

Iodol.—Dr. R. N. Wolfenden, of the London Throat Hospital, urges the claims of iodol as a substitute for iodoform, in an article in *The Practitioner*, No. 5, 1887. Its merits are that it is odorless, or nearly so, tasteless, produces no constitutional effects, contains nearly as much iodine as iodoform, and parts with it more readily. It is antiseptic, anæsthetic, a promoter of granulation and healing, and it arrests suppuration and deodorizes foul secretions.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 20, 1887.

A NEW MODE OF TREATING BURNS.

PROFESSOR MOSETIG has recently called attention to a method of treating burns and scalds which he has adopted in forty-eight cases during the last five years, with superior results. The treatment of this class of injuries undergoes periodically certain changes in detail, and almost always differs in different hospitals and with different surgeons. Erichsen covers the injured surface thickly with wheaten flour. At Guy's Hospital, carron oil was for a long time chiefly used; and at the London Hospital, zinc ointment spread on lint.

In this country, white lead was recommended by the late Dr. Gross, and in many hospitals solutions of bicarbonate of soda have been largely employed. Mr. Thomas Bryant speaks of his great success, in burns of all degrees, with an ointment of vaseline and boracic acid, spread on lint.

One per cent. solutions of creasote are highly recommended.

All these methods involve the application of two leading principles, viz., the exclusion of air and the changing of dressings as little as possible.

Professor Mosetig does not introduce anything new in these respects. The iodoform has, like the creasote solution, a twofold action, that of an analgesic and antiseptic. The claim is that patients obtain ease a few minutes after the application of iodoform to their burns, and are soon fit to be moved. They recover more rapidly, with only moderate and consequently less exhausting discharges, and with smoother cicatrices, than those differently treated; and if there is no possibility of saving life, its last hours are made less painful. There is no danger from iodoform-poisoning so far as experience shows. This is perhaps because Professor Mosetig uses the agent in small amounts.

According to the description given in the *Wiener Med. Press* (1887) (*Journ. of Cutaneous and Genito-urinary Diseases, London Medical Record*), he either does not employ the powder at all, or when so in rare instances; he sprinkles it by means of an insufflator in very thin layers, only on those places where the integument has been burnt in its whole thickness, and has assumed a parchment-like appearance. As a rule he covers the injured parts directly with compresses of iodoform-gauze, not prepared in the usual way, by thickly dusting the gauze with the powder, but by impregnating with an etheric solution of iodoform, the purified gauze which has previously been freed of grease. He proceeds in the following manner: After opening and excising the vesicles, and cleaning the burns with cotton-wool, which had been steeped in a half per cent. solution of table-salt, and well pressed out, he covers the wounds with dry compresses consisting of several layers of iodoform-gauze, prepared as stated above, of corresponding size, which are exactly and smoothly laid over the whole surface of the injury. Over this an equally large or somewhat smaller piece of gutta-percha tissue is placed, taking care that it does not form folds or creases. The whole is wrapped in a very thick layer of medicated absorbent cotton-wool, which overlaps to a great extent the compresses, or, better, surrounds the whole limb or injured part of the body. This cotton-wool is finally fixed by several turns of bandages, which at the same time exert a gentle pressure. This simple dressing, which, moreover, has the advantage of taking up very little time, is allowed to remain, without being changed, as long as possible, *i.e.*, as long as cleanliness permits, and no rising of the temperature takes place.

The secretions from the wound drain off beneath the gutta-percha tissue, and are taken up by the absorbent cotton-wool. Slight staining of the bandage is no sufficient indication for renewing the dressing, which ought to be permanent; in case of real imbibition and offensive smell only the external dressing has to be removed and changed; the iodoform-gauze, and the gutta-percha covering, however, should not be interfered with.

In case, in the meanwhile, fever should set in, which betrays by its character septic causes, generally the demarcation and separation of the mortified part having commenced, or a retention of the secretion of the wound having taken place, the dressing must be removed, the abscess opened, and free discharge of the pus secured; the mortified shreds and the eschars must be removed by means of forceps and scissors. The new dressing is put on in the same manner as the first one.

The impermeable covering of gutta-percha tissue is very essential, and ought never to be omitted, because the drying on and sticking to the wounds of the gauze, stiffened by the imbibed secretions, is always injurious, and may moreover cause, like a scab, retention of the secretion. The discharges may be allowed to dry in the external portion of the dressing, but never on the wound itself.

By the permanent iodoform-dressing the infection, both by the air and by contact, is prevented, and burns of the second degree, as a rule, heal under a single dressing. In burns of the third degree aseptic separation of the eschar, with but slight secretion, frequently takes place, and even if the latter be not the case, the granulating surfaces heal in a far shorter time, and the cicatrization is smoother, more even, and altogether less disfiguring than in non-aseptic treatment.

In burns and scalds of the face an iodoform vaseline-ointment is used (1 to 20) with a gutta-percha mask.

MAINE AND ITS MEDICAL REGISTRATION LAW.

THE medical men of the State of Maine are in a state of mind over their medical law. This is very natural, for the governor says that no such law exists, while the

Maine doctors themselves are convinced to the contrary.

It seems that the last legislature passed the bill providing for medical registration, by a large majority, and sent it up to the governor for his signature. The governor appended it in due form and sent the bill to the secretary of state, who recorded it as a statute. The governor then met certain friends, who advised him to veto the measure. The vacillating executive sent for the bill, scratched off his signature, and returned it to the legislature with a veto. The record in the secretary's office was also erased. The Board of Censors of the Maine Medical Association investigated the matter, and put in a claim, supported by good legal authority, that the bill, having once been made a law by the governor could not be unmade, and that the law does now, in fact, exist. The question is an interesting one, and it appears to us that the Board of Censors have decidedly the best of the argument.

THE FEE FOR TREATING VENEREAL DISEASE.

Referring to the letter of Dr. J. E. Free which appeared in The Record of July 16th, on the subject of the fee in a case of gonorrhœa, Dr. P. L. Myers, of Fostoria, O., asks if it is not out of keeping with the boasted dignity of our profession "that we charge $20 as retainer in gonorrhœa?

"Why," he says, "take a retainer, or at least more of a retainer, in gonorrhœa or syphilis, than in other diseases?

"Is it a penalty *we* inflict for crime? Are we judge, sheriff, and public school fund?

"If not, by what right, human or divine, do we charge an extra price to a mortal, unfortunate (I use the word none too charitably) enough to contract a disease which is notoriously painful, tedious, and disgusting." After further amplification of this point, he adds: "I know the usual argument in palliation of our custom. This disease comes through crime—the source is dishonesty," etc. But "our plain duty as physicians is to relieve sufferings resulting from disease, to charge therefor in proportion to time or service rendered—regardless of cause—with charity."

Our correspondent's argument is in the main a sound one, and deserving of attention. But with regard to the matter of criminality we must be permitted to say that his ideas are a little mixed. Fornication, from which, as a rule, gonorrhœa and syphilis come, is not a crime in any civilized country, but it is regarded as a sin by the Christian and Hebrew religions, and a vice by all ethical teachers of the higher sort.

The physician has no right to judge or punish by charging a heavier fee for treating venereal than for treating other diseases. Indeed, the laying down of rules for the taking of a retainer in one disease and not in another is wrong, and the custom should be abolished.

The feeling which physicians have, however, that fees for treating venereal diseases should be ample and should be promptly paid is a justifiable one. It is impossible to regard the man sick from an expensive debauch with exactly the same feelings as we do the man who gets ill while working for the support of his family. The sexual passion is normal, but man distinguishes himself from the brute by controlling it.

THE RECREATIONS OF THE PHYSICIAN.

It is not so very long ago that a physician who had any other occupation than that of treating the sick, or who dared to let the public know that he sometimes found other means of passing his spare moments than in the study of his medical books and journals, was regarded as a man with a hobby and a rather dangerous person to whom to intrust the care of one's health. It was said that the practice of medicine was a hard and difficult task, and one that demanded the undivided care and study of a lifetime. And if one was known to spend some of his time in other pursuits, literary or commercial, he was supposed to be wasting time that belonged to his profession. People forgot that recreation is necessary to every man, and the more necessary as the man's avocation is the more fatiguing. And they also forget what is equally true, that recreation is not necessarily idleness, but rather, and far more, a change of occupation.

But physicians did take recreation then as well as they do now, and they often took it in the same way that many do now, although, influenced by public opinion, they did not often dare to publish the results of their recreative occupations. Literature was thereby a loser, and medicine gained nothing. It is a hopeful sign at the present day to see physicians appearing with increasing frequency in the world of general and scientific (non-medical) literature, and we believe that medical science will be by no means a loser by these occasional excursions of its students into other fields.

These random reflections have been caused by the perusal of two entertaining little pieces written by a physician who is already well-known to medical literature.[1] The comedies are very amusing and "summery," are besides very bright, and afford a pleasant half-hour to the reader wearied with microbes and ptomaines, intubation and phthisis, the properties of strophanthus, and the uses of antifebrin. As we have said before, the physician is generally well fitted, by his habits of close observation of men and things, to succeed in descriptive writing, and we are glad that medical men are beginning to give to the world the products of their hours of recreation as well as the results of their more serious studies within the limits of their professed vocation.

POSSIBLY A NEW DISEASE.

In a paper read before the Royal Medical and Chirurgical Society on June 14, 1887, Mr. Jonathan Hutchinson reported several cases of a disease which it was believed had never before been described. The paper was of considerable length, but we can refer here only briefly to the more prominent features of the disease as observed and pictured by the author.

The affection begins by an inflammation and superficial ulceration of the lips and mouth, and this is followed sooner or later by some form of skin-disease. The tendency of the affection, when unmodified by treatment, seems to be toward a fatal issue, though the treatment is simple and apparently very efficacious. The form of skin-disease may vary, but the hands and feet are the parts usually affected, and the nails seem especially

[1] Two Comedies: An Ill Wind; An Abject Apology. By F. Donaldson, Jr. Boston: Cupples, Upham & Company. 1887.

prone to suffer. In some of the observed cases the eruption consisted of bullæ, upon which supervened free papillary outgrowths.

The patients attacked were usually in middle life or in the early senile periods, and all the best-marked cases occurred in men, although some mild cases were observed in women. The cause of the malady seems to be obscure. The disease, at least in its severer forms, appears to be met with only in those residing in the country, but no evidence could be found to justify the suspicion that the affection might be due, perhaps, to contagion from animals. The cases hitherto observed have been only in those in the more comfortable walks of life.

Various drugs and methods had been tried to no purpose, when the author and Mr. Pollock simultaneously, but independently, discovered the utility of opium. Before the opium-treatment was tried, death was very commonly the result, but since that time every patient so treated has recovered.

Mr. Hutchinson did not venture to express any positive opinion as to the nature of the disease, but he thought that it was probably, or possibly, allied to other forms of skin-disease occurring in early senile periods in conditions of disturbed health. At such times it is not uncommon to meet with certain peculiar forms of pemphigus, psoriasis, lichen planus, and pityriasis rubra. In support of this suggestion, the author reported a case of an elderly lady who had a kind of eczema-psoriasis of the hands and scalp. She lost all her nails and hair, and was rapidly failing in health despite various methods of treatment, but finally recovered quickly and completely under opium. Her case did not belong to the group described in the paper, as she had never at any time had an inflammation of the mouth, but in other respects the disease seemed to be similar to the cases described, and the beneficial effects of opium were very clearly manifested.

A Self-retaining Laryngeal Mirror.—Dr. Karl Roser has invented and described in the *Centralblatt für Chirurgie*, July 16, 1887, an apparatus for retaining the laryngeal mirror in position, thus leaving both hands of the operator free to make the necessary manipulations. The mirror is retained by a watch-spring passing over the head, and its position is changed as may be desired by means of a thumb-screw resting against the forehead. Naturally, it can be used only in well-trained patients whose fauces are not over-sensitive.

Warn Your Patients before Raising Your Fees.—A French law journal reports an unsuccessful suit of a physician to recover the amount of his bill for a confinement. The bill was for 200 francs, and the husband acknowledged the services rendered, but refused to pay more than 100 francs, which was the amount that he had paid the physician for attendance on his wife in previous confinements. The court decided that he was indebted to the extent of only 100 francs, as the physician had not notified the patient of the increase in his charges.

Bavarian Quacks.—The number of quacks in Bavaria in 1886, according to the official statistics, was 1,349, or 24.7 per 100,000 inhabitants.

News of the Week.

The International Medical Congress.—We have received several inquiries concerning the coming meeting of the International Congress. We take occasion to answer as many as possible, giving the latest information we are able to obtain. Reduced rates of fare have been made on most of the large railroads to Washington on the certificate plan; one full fare going and one-third fare returning. It will be necessary for these certificates to be procured before starting and have upon them the receipt of the railroad agent for the full fare to Washington. Members intending to attend the Congress should, as soon as possible, make application to J. W. H. Lovejoy, M.D., Chairman Transportation Committee, No. 900 Twelfth Street, Washington, D. C., for blank certificates of the Association over those roads they intend to travel, and the blanks will be forwarded at as early a date as they can be obtained. A separate certificate will be required for each person. (The reduced rates apply not only to members, but to their families. Certificates should be secured as soon as possible—one for each person.)

Form to be filled up by applicant for membership in the Congress:

Name in full .....
Post-office address.....
If in a city, give also street and number .....
If in the country, give also name of the county.....
State .....
Province.....
Country.....
If a delegate, state from what country or society.....
Practice, general or special.....
If special, name the branch.....

This form must be filled out carefully and presented (with $10) to the Chairman of the Committee on Registration, J. M. Toner, M.D., No. 613 Louisiana Avenue, Washington, D.C.

Hotel rates at Washington—At the Arlington, Riggs House, Willard's, Metropolitan, and National the rates are from $3 to $3.50. Other hotels, conducted on the European style, will furnish rooms at $1 and $2 per day. Good lodging-houses will also furnish rooms from $1 to $1.50 a day.

Russification of the University of Dorpat.—The Russian authorities recently ordered that instruction should be given in Russian at the University of Dorpat, whose official language has hitherto been German. The professors all sent in their resignations, and now the government announces that the change will not go into effect until the expiration of three years.

Burial by Machinery.—An Austrian inventor is said to have devised a means of interment by machinery. The coffin, instead of being lowered by the more or less clumsy means now adopted, is placed on a platform (the grave being concealed by black drapery), and, by pressing a spring, the platform and coffin sink slowly into the grave.

Female Medical Students in Paris.—There are now 108 women studying medicine in Paris, of which number 83 are Russians, 11 English, 7 French, 3 Americans, 2 Austrians, 1 Roumanian, and 1 Turk.

Cremation in Brazil.—An imperial decree has recently been promulgated in Brazil, making cremation compulsory in all cases of death from yellow fever The state will provide the crematory furnaces and will pay all the expenses attendant upon this mode of disposal of the bodies.

Photo-micrography.—The third International Photographic Exhibition, which is to take place in October next, will comprise a section open to members of the medical and other learned professions, for clinical studies, micro-photographs, natural history photographs, etc.

A Faster Who did not Fast.—The man Cetti, who has gained considerable notoriety by his alleged feats of fasting, has been detected eating lozenges containing a concentrated nutritive material. When the fraud was exposed by some medical students who were watching him, he gave up the job and started, presumably, for a restaurant.

Human Fat in Medicine.—In answer to a correspondent, the *Medical Press and Circular* refers to Motley's "United Netherlands," vol. iv., page 74, in which he says, when describing the repulse of the Spaniards at Ostend and Antwerp, in 1585, and the terrible slaughter consequent thereon, that "the Dutch surgeons sallied forth in strength after each encounter and brought in great bags filled with *human fat*, which was then esteemed the sovereignest remedy in the world for wounds and diseases."

Theine in Neuralgia.—On account of the low solubility of theine, Dr. Mays advises its use according to the following formula: Thein., sod. benzoat., āā 3 j.; sod. chlorid., gr. x.; aquæ destillat., f ℥ j. M. Sig.: Six drops equal half a grain of theine. Dose, from three to twenty drops.

Chrome Yellow has been extensively used to color buns by the Philadelphia bakers. These enterprising gentlemen may not be able to paint the lily, but they can color the flour. Two of them have been put under arrest.

Pasteurism in Austria.—The Austrian Chamber of Deputies has passed a resolution praying the government to provide facilities, at the Vienna General Hospital, for making preventive inoculations in threatened rabies.

An Hydrological Caravan.—The French Society of Hygiene has voted to organize what it calls an "hydrological caravan." The members propose to visit the numerous spas in Central France, and they are promised a fine time by the authorities in each of the places visited. It will doubtless be very convenient for the travellers, after testing the vintages in the evening, to have ready access to the natural carbonated waters the following morning.

A Missionary Hospital at Teheran.—The American missionaries in Persia have been authorized by the Shah to establish a hospital at Teheran, and the physician of the mission has been named by the Shah, "Grand Officer of the Order of the Lion and of the Sun of Persia." With a medical director bearing such an honorable title, the hospital ought to be a success.

Egg-Albumen for Culture Media.—Drs. Tarjanoff and Kolesnikoff have utilized the white of egg for culture, and have found it very satisfactory. The egg is soaked for from five days to two weeks in a five or ten per cent. solution of caustic soda or potash. At the end of this time the albumen is solidified and transparent. Heat can then be used for the purpose of sterilization without causing any change in the albumen.

Dr. Baratoux has been commissioned by the French government to visit the United States and Canada to study diseases of the larynx, nose, and ears, as taught in America, and especially to gather data concerning hay-fever.

An "M.D." in Nine Months.—Dr. Fisk, writing to the Boston *Medical and Surgical Journal*, states that he knows of an instance in which a young man attended the fall course of lectures for 1886–87 at the Denver University, then came East with his certificate and attended a lecture course in the University of ———, situated "among the hills of New England," and was there graduated in medicine on July 15th, nine months and eight days after he had begun his medical studies. Comment is unnecessary.

A Criminal Surgical Operation in Chicago is the obliterating of birth-marks, when such teratological defects serve to identify a child. The court rules it to be tampering with the evidence. A physician and a woman have been fined and sentenced to thirty days in prison for this novel offence.

A Quack Come to Grief.—A bone-setter in France undertook the treatment of a man with nasal polypus, promising to cure him, and exacting an advance of five hundred francs. He then covered the man almost completely with blisters. After the patient had tired of this energetic treatment he complained of the quack, who was sentenced by the court to three months' imprisonment. The bone-setter's wife, who had assisted him, was sent to prison for two weeks.

King Kalakaua is said to take quite an interest in science. His friends say that the Hawaiian Legislature having made an appropriation for the purpose of ascertaining the genealogy of the Hawaiian chiefs, and this inquiry having terminated, his Majesty Kalakaua has decided to apportion the remainder of the appropriation for the purposes of science.

The Medical Department of Ann Arbor University.—There is some talk of removing the clinical branch of the Michigan University Medical Department from Ann Arbor to Detroit.

Trimethyl Carbinol.—Dr. Shapiroff, of St. Petersburg, has been experimenting with this new drug, and finds that it lowers the blood-pressure. diminishes the excitability of the nervous centres, and causes a profound and calm sleep. He thought it would prove to be of great value in alcoholic insomnia and neurasthenia. He employed it in doses of from five to fifteen drops twice a day. Dr. Shapiroff has also experimented with dimethyl carbinol, and finds that it exerts a more rapid and a more intense action even on the nervous system than does the trimethyl carbinol.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 8, 1887,

T. MITCHELL PRUDDEN, M.D., PRESIDENT, IN THE CHAIR.

DR. PUTNAM-JACOBI presented in behalf of a candidate a specimen of *acute atrophy of the stomach, with fatty degeneration of the heart.*

DR. DUDLEY presented

THE UTERINE APPENDAGES

in the case of an unmarried woman, aged twenty-two, with the following history: At the age of six years she had had small-pox, from which she made a good recovery; from six to twelve years of age she had some of the exanthemata and diphtheria; at the age of twelve she showed nervous symptoms, and would occasionally faint, especially if in a crowd; at times she complained of headache; at maturity her headache grew steadily worse, and was most severe at the menstrual period. She was then put under the care of a physician who made the diagnosis of hysteria; another physician treated her for rheumatism; a third for chronic meningitis; a fourth applied electricity, which made her condition worse; a fifth treated her for rheumatism of the brain. Finally she came under the care of Dr. Hammond, who treated her for brain-congestion, together with other symptoms. She had never shown any signs of insanity; she was always of a lively disposition when not in pain; she had never had a true spasm. Dr. Hammond placed her in the care of Dr. Dudley, who found that she was well nourished, that her menses were regular, lasting from two to four days, the flow being moderate. She suffered no pain except in the head, but lately had had pain in the side, one week before, and one week after menstruation. She had taken large quantities of medicine, and had been treated by almost every means for relief of her nervous condition. She had been a masturbator for years, but said she had given up the habit some months past. The vulva was so hyperæsthetic that a physical examination was very difficult. The meatus was surrounded by a large caruncle. From a superficial examination he found the uterus retroverted, and the ovaries and tubes correspondingly low. At a second examination, without ether, he was able only to replace the uterus. Saturday last, he examined her under ether; the left ovary seemed to be small; the right ovary seemed to be somewhat enlarged, and very sensitive. After consultation, and having obtained the previous consent of the patient, and of her brother, who was a physician, it was decided to make an exploratory operation. The right ovary was found somewhat enlarged, and contained a cyst about the size of an English walnut; the tube was tortuous, and the fimbriated extremity was bound down below the ovary; the ovary and tube were removed. The left ovary was found to be small, and contained a small cyst. The tube was tortuous and bound down to the pelvic floor, and quite close to the intestine; beneath it was a large varix; this ovary and tube, together with the varix, were removed. The patient had since done well.

A point of special interest in the case related to the

VARICOSE VEINS.

This was the third case of the kind which he had operated upon during the past year. In all, there had been failure to relieve the reflex symptoms by various ordinary measures, such as repairing a lacerated cervix, curetting for a fungous condition, the administration of drugs, etc. In the first two cases the pain in the side and other reflex symptoms disappeared after removal of the ovaries and varix. The ovaries were not much enlarged. In the third case, the operation had very recently been performed. Dr. Dudley thought that inasmuch as a varicocele in the male might give rise to almost all kinds of reflex symptoms, so also might an analogous condition exist in the female.

DR. PUTNAM-JACOBI thought it would be interesting to make a microscopical examination of the small ovary, and learn whether or not it was the seat of interstitial ovaritis. Two years ago she reported three cases in which the ovaries did not present any very marked lesion when examined macroscopically, but when examined microscopically there were found degeneration of the arteries and the signs of interstitial ovaritis, and she thought this was much more the cause of the severe nervous symptoms which had existed than was any slight cystic degeneration. In fact, a cyst of considerable size might exist and cause no suffering or tenderness when pressure was made over the abdomen. She referred to the case of a young lady who, before coming East, had undergone at least one year's continuous treatment in a Western State for symptoms related, presumably, to an existing enlargement and prolapsus of both ovaries. The treatment by galvanism was continued, and an attempt was made to replace the ovaries, and a boro-glyceride cotton tampon was introduced into the vagina. At first this local treatment seemed to be beneficial. But the relief proved to be only temporary, and the tampon after a time seemed to cause irritation. Local treatment was then discontinued two or three months, during which time the patient received simple massage, to some extent electrical massage, the cold pack with rubbing, and general treatment. Under this plan the pain in the back, and the nervous symptoms generally had entirely disappeared, also the tenderness on pressure over the ovaries, although the organs remained prolapsed and enlarged. Dr. Jacobi had seen at least two or three cases in which the

ENLARGED AND PROLAPSED CONDITION OF THE OVARIES

had continued after relief of all the apparently associated symptoms.

DR. DUDLEY'S specimen was, at his request, referred to the Committee on Microscopy. Referring to the remarks of Dr. Putnam-Jacobi, he expressed the belief that cotton tampons with boro-glyceride produced their beneficial effect by causing contraction of the vessels, and reducing uterine congestion. He did not think that in his case there had been acute ovaritis; the patient had not complained of pain in the region of the ovary until very recently. As to the relief of symptoms by cotton tampons containing glycerine, he had two cases of prolapsus of both ovaries and tubes in which such treatment would cause almost entire disappearance of the symptoms for a month or two, but they would return with each new exposure to cold, overexertion, etc.

DR. PUTNAM JACOBI thought that in the case related by her the uterus was perfectly healthy, and the tampons had produced only slight relief, whereas the general treatment had caused entire cessation of the subjective symptoms.

THE PRESIDENT said it was so seldom one found a normal ovary that it was difficult to obtain a sufficient number for demonstration before students. Interstitial ovaritis was very common even in cases in which there had been no history of symptoms associated with it during life.

DR. W. P. NORTHRUP asked Dr. Dudley whether he had noticed in his cases any of the changes in the features, voice, growth of hair on the face, etc., alleged to take place after removal of the ovaries.

DR. DUDLEY replied that he had kept his cases under observation as long as possible, but in none had he noticed a change in the voice, in the growth of the hair on the face, or in any other respect, excepting that usually there was an increase in flesh, and some complained of flushes in the head after removal of the ovaries.

BONY EXCRESCENCES ON THE INNER SURFACE OF THE CRANIUM.

DR. THACHER presented the skull of a colored woman, about thirty-five years of age, whose clinical history was

meagre. She had complained of severe headaches for three years, which she thought were due to menstrual troubles. There were chronic changes in the kidneys, but no diagnosis of kidney-disease had been made by the physician in charge. The urine had, according to the report, been of fairly high specific gravity, and contained no albumin. There was no history of venereal disease. During the past three months the patient had had occasional attacks of vertigo, with loss of consciousness and falling to the ground. The attacks became more and more frequent toward the end of life. She gradually weakened and died. The diagnosis made was epilepsy. There were found at autopsy bony excrescences on the inner surface of the frontal bone, and some calcified masses in the dura mater. The dura was closely adherent to the skull.

REMOVAL OF RIGHT HALF OF LOWER JAW BY SLOW ENUCLEATION.

Dr. Joseph W. Howe sent a patient with the following history: Thomas R——, twenty-three years of age, was admitted to St. Francis Hospital with the following symptoms. On October 4th he received a severe blow on the under surface of the chin, which exposed the bone. The wound was sewed up at St. Luke's Hospital, but failed to unite. The jaw afterward became very much swollen and painful, and he sought admission to St. Francis Hospital. Dr. Howe made an examination in the early part of November, and found an extensive swelling extending from the symphysis to the posterior part of the ramus of the jaw on the right side, and a small hole running up under the chin behind the jaw, which led to the dead bone. The teeth on the affected side were loosened, and the alveolar process stripped bare and rough and bathed in pus. Pressure on the outside, over the jaw, forced a quantity of pus out, both from between the periosteum and bone and external to the periosteum. The periosteum was separated along the upper line of the jaw back to the ramus, and in some parts had been completely destroyed. The lower teeth were removed from the jaw the following day, and a portion of the periosteum separated. This process of separating the periosteum from the bone was repeated at intervals for several weeks, while the parts were thoroughly cleaned and the patient's general health was kept up by tonics and stimulants. With the stripping of the bone, the periosteum gradually thickened so as to increase the swelling on the affected side. Three weeks previous to the first operation he made a careful examination under ether, and separated the greater portion of the periosteum and other tissues from the bone. Pieces of lint steeped in carbolic acid and glycerine were placed on each side of the dead jaw, and the patient was allowed to return to the ward. More swelling and fever followed the operation. On the following Monday he completed the operation, removing the last attachment at the symphysis and pulling out the diseased jaw, leaving behind a good basis for a new jaw in the ossifying periosteum. The slow enucleation of a diseased jaw is a comparatively simple process; very little force and very little cutting are required to remove it. The patient has now a new jaw, which has grown from the old periosteum.

Dr. W. P. Northrup presented specimens from a

CASE OF INTUSSUSCEPTION,

with the following history: The patient was a boy aged five months, who was cared for in his illness "between" two or three physicians. The child was well nourished, large of his age, without previous disease. Forty-eight hours before death the only record of him is that he had "severe diarrhœa," with vomiting. During the last twelve hours the vomiting increased in severity, and the diarrhœal discharges became bloody mucus. The patient cried shrilly and had "inward convulsions." The head, rolling constantly from side to side, had worn the hair from the occiput.

On autopsy the abdomen was found tensely distended. The contents of the intestines were yellow, grumous material, with castor-oil, which had recently been administered. The distention was found to be wholly of the small intestine. The stomach was empty, and colon and rectum were collapsed. Lying in the axis of the transverse colon was the tumor shown, which was four inches long, an inch and a quarter thick, round, firm, and of a bluish color, and was found to be an invagination of the cæcum into the transverse colon. The latter was in normal condition; the former deeply congested.

From the hepatic extremity protruded the ileum and mesentery, and a half-inch of the two-inch-long appendix vermiformis. The tissues were deeply congested and dusky. The two innermost layers, lying with their peritoneal surfaces together, were adherent, with tender, recent attachments. On inspecting the splenic extremity, the outermost layer, the transverse colon, was found to be normal. On stripping back the outer layer, the everted and invaginated cæcum was seen. It is like stripping back the prepuce and laying bare the glans.

The color of this packed invagination was almost black; the epithelia macerated and easily swept off, and its surface smeared with tenacious blood stained mucus. The gut was believed to be not gangrenous.

The Society then went into executive session.

Stated Meeting, June 22, 1887.

W. P. Northrup, M.D., Vice-President, in the Chair.

Dr. John C. Peters presented *portions of intestine* received from Dr. Middleton Goldsmith, of Rutland, Vt., which were interesting only with regard to the history of the case. [The stopper of the bottle had become loosened and allowed the specimens to get dry during transportation.]

Dr. J. H. K——, of Rutland, was taken ill at 9 A.M., June 4th. Dr. Caverly, was called immediately and found him suffering from great pain in the right iliac region. There was no swelling—no tympanites. The bowels had a natural feel.

He described his case as occurring in this wise. He had occasion, just before, to take an enema, which he gave himself. There was no pain during the injection. The first effort to pass anything from his bowels was attended with some pain; the second with excruciating pain.

At that time Dr. Caverly found him—besides in severe pain—cold to the elbows and knees and pulseless, and his face had the ashen hue of death. He was crying out in severe pain. Dr. Caverly immediately gave him two-thirds grain morphia sulph. hypodermatically, and applied hot-water bags to the extremities, and sent for me.

I found him free from pain, and in answer to my question he said he was in no pain then, and on asking how he had been for several days, he said he had been ailing for some time with indefinite pains through his bowels, with a good deal of pain in the right iliac region for three weeks, and that was all, except that his belly was sore all over.

The first question was, what was the injury? We were not aware *what* it was nor *where* it was. The facts seemed to point to some injury done to the right groin, which looked like a *rupture*, because of the suddenness of its onset, and of the *intestine*, because of the severity of the pain.

We could not help thinking, after witnessing the first shock, that this was a fatal injury—a tear or something of the kind. We did not feel sure, although the symptoms looked that way. We gave opium to narcotism, feeling that that was the only hope of adhesive inflammation and not suppuration. He died at 5.30 A.M., June 8th.

At the post-mortem examination there was found almost universal adhesive inflammation in the right side of

the abdominal cavity. There was nothing in the cavity but about a half-teacupful of pure serum. The adhesions were so complete that the parts had to be torn from each other by force. A profile of the torn gut showed the usual long hairy-like attachments. The gut adhered to the liver, and wherever a knuckle of small intestine came in contact with the cæcum or ascending colon it had adhered. After taking out the gut it was filled with water and then pressed with the hand when it was found that it gave way slightly under the grasp as though there was a small rent. The whole length of the gut was examined—the ducts of the liver, the gall-bladder, kidneys, ureters—and they were all intact. There was no injury from the nozzle of the syringe. Bladder and urethra were sound. The duodenum and jejunum were examined; all were sound.

Dr. H. J. Boldt presented the heart and lungs just taken from the body of a boy eight years of age, which showed

PNEUMONIA AND PERICARDITIS.

that had complicated *traumatic peritonitis*.

On June 12th the patient received a blow upon the belly from the fist of another boy. He went home and went to bed, complaining of intense pain in the abdomen, which began shortly after receiving the injury. His parents, on the next morning, reported that he had had considerable fever during the night and that he complained more or less of pain in the abdomen. On June 13th, Dr. Boldt found him with high temperature, tenderness over the entire abdomen, especially marked in the right iliac region, and he diagnosticated traumatic peritonitis. In the course of two days, however, pneumonia developed, which progressed until the whole of the right lung became involved; later, the left lung gave evidence of some consolidation. The consultant thought that the right pleural cavity contained fluid, and Dr. Boldt aspirated, but obtained only twenty grammes. During the progress of the pneumonia, the peritonitis was lost sight of. The patient died on the morning of June 22d.

The autopsy revealed diffuse peritonitis, pleuro-pneumonia involving the whole of the right lung, a few ounces of fluid in the left pleural cavity, with a small amount of pulmonary consolidation and marked pericarditis.

Dr. Boldt also presented a specimen of

PYO-SALPINX

on which he operated very soon after rupture of the sac. It was from one of *three* cases in which he had operated soon after rupture. In the first two, peritonitis developed and killed the patients. The third case terminated in *recovery*. The patient came under his observation on June 5, 1887. He had previously seen the patient and made his diagnosis, and intended to operate, but suddenly, on the morning of the date mentioned, she was seized with severe pain in the lower part of her abdomen, accompanied by some vomiting, and she was compelled to remain in bed. There was considerable tenderness, but no other evidence of general peritonitis. On palpation it was also found that the tube, which could be felt distinctly on previous occasions, had collapsed and disappeared substantially. Dr. Boldt operated within two hours, and found that the Fallopian tube had ruptured. There was considerable localized redness about the pelvis, but no peritonitis. The abdominal cavity was thoroughly cleansed by irrigation, and the patient made a good recovery.

Dr. W. P. Northrup presented microscopic sections of

PRIMARY EPITHELIOMA OF THE CONJUNCTIVA,

made from a growth that was removed by operation from the eye of a private patient, a girl three years and two months old, whose parents were living, young and healthy, except that the mother had frequently suffered from obstinate eczema.

The child had a light complexion and clear skin, and has always been healthy, well nourished, and vigorous.

October 14, 1887, she was presented for treatment. There was at the nasal margin of the left cornea a nodule the size of a pin's head, smooth, round, and pale red, and leading to it were three or four enlarged vessels. There were slight lachrymations, photophobia, and diffuse redness of the eye. There was no history of traumatism.

The pathological anatomy was judged to be a simple hyperplasia of gland-tissue at the limbus corneæ, a phlyctænula, which would soon part with its superficial epithelium, empty its contents, and speedily repair. A favorable prognosis was given, the child was seen every day, but at the end of a week no progress had been made toward recovery, the tumor, seemingly, remaining unchanged.

Dr. Agnew then saw the case in consultation, and confirmed both the diagnosis and the prognosis.

In his opinion the hyperplasia instead of resolving itself, remained as a simple hyperplasia, and would at length return to its normal condition with possible permanent thickening of trifling amount.

In the second week the tumor enlarged somewhat, being perhaps twice as large as when first seen, and at this time it was about four millimetres in diameter; its base was round, defined, lying partly upon the cornea, partly upon the sclerotic, movable moderately; its surface was nodular and fissured (cauliflower excrescence), and at its summit there was loss of substance

PRIMARY EPITHELIOMA.

At this time the case was seen by Dr. Agnew and Dr. Webster, who agreed on the diagnosis of epithelioma, and advised prompt removal.

November 19th, Dr. Agnew, assisted by Dr. Webster, removed the growth and cauterized the subjacent tissue.

The conjunctiva was brought together by stitches and the eye closed, having upon it a pad of absorbent cotton lightly held beneath a shield. The patient made a prompt and satisfactory recovery. At this time, seven months after the operation, there remains a smooth cicatrix about four millimetres in horizontal length, and less in width, lying partly upon the cornea and partly over the sclerotic. Upon the cornea it has a pearly opacity visible about three feet distant. The enlarged blood-vessels are no longer seen, and there is no evidence that the scar is not free from any suspicion of returning disease.

The eight microscopic sections shown constituted nearly the whole of the tumor. The microscopic examination of the specimen revealed that it was an epithelioma. This was the opinion of Dr. Delafield, who had carefully studied the sections.

Remarks.—Epithelioma in this locality, whether of the cornea or conjunctiva, is commonly secondary to cancer of the lids. In the case here reported it is primary. In its early stage it is easily mistaken for phlyctænula, though it is attended with less irritation and congestion, lachrymation and photophobia. Its growth is slow at first, then rapidly spreading and invading deeper tissues, and may speedily destroy the organ.

The treatment consists in removing it radically as soon as the diagnosis is made.

The prognosis is bad. The growth usually returns, and speedily.

The present case has passed the seventh month without a symptom of returning, and the prognosis is now considered good.

The Society then went into executive session.

"Fortschritte Der Medicin."—The editorial management of this journal has, since the death of Friedländer, passed into the hands of Professors Karl Weigert and Heinrich Unverricht.

Correspondence.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION AT DUBLIN.

(From our Special Correspondent.)

DUBLIN, August 6, 1887.

THE meeting which concluded yesterday has been an unqualified success. It has been numerously attended, has progressed harmoniously, and much scientific work has been done. The rearrangement of the sectional work has been very beneficial. The sections are now more numerous, each session is longer in duration, and the morning is now devoted to this—the real work of the meeting. The Association has held its annual meeting in Dublin before, but that was twenty years ago. It goes without saying that the Association has been through a period of great growth since then, but its expansion year by year is now a well-worn tale, repeated year by year at successive annual meetings.

The proceedings commenced on Tuesday morning at half-past eleven—another innovation, for heretofore the first move has been made in the afternoon. After the retirement of Dr. Withers Moore from the presidential chair and the installation of the new President (Dr. Banks), the usual formal business followed. The threadbare question of the payment of the expenses of members of the Council again came up. In despair, it would seem, the Council had devised a plan of payment, not of railway-fares, but by a sliding scale of fees varying from one to five guineas, according to the distance. After some stormy discussion this section of the report was thrown out, and the principle of "no pay" again affirmed by a large majority. At the afternoon session, Sir Thomas Crawford, K.C.B., M.D., etc., Director-General of the Army Medical Department, made a lengthy statement as to the question of "relative rank" of army surgeons, as to which much discussion has taken place of late. He deprecated the position taken up by the *British Medical Journal* in the matter, and asserted that no discontent had been brought to his knowledge as existing among army medical officers at its abolition. For his part he did not believe that any change for the worse had been made in the position of army surgeons, but rather the contrary. In fact, what had been done had been done with his own sanction. Army surgeons never had had any other real rank than that assigned to every army medical officer in his commission, viz., "the rank of surgeon." That rank every army surgeon still had. He did not believe that there was any desire among medical officers in the army for military titles. Mr. Ernest Hart defended the report, and several lively passages took place between him and Sir Thomas Crawford. The latter proposed to refer back to the Parliamentary Bills Committee all that portion of their report dealing with this subject. Mr. Hart ultimately said he would not oppose this reference, if by it further inquiry, not censure, was implied. After considerable discussion by various speakers this was accordingly done.

At the evening meeting the chief event was, as usual, the reading of the Presidential Address. This had evidently been prepared with great care, and was well worthy of Dr. Banks' distinguished reputation. It was, however, of a nature not readily lending itself to being epitomized. After some introductory observations, he proceeded to give a sketch of the history of medicine in Dublin. The University of Dublin with its College (Trinity), the College of Physicians, and the Dublin School of Physic were referred to in turn, and their rise and progress sketched. Nor was the younger Royal University of Ireland, although of such recent origin, forgotten. He traced back the University to the days of Queen Elizabeth. Seven years after its foundation it was recorded in the College Register that a *concordatum* of forty pounds a year was granted by the government for a "physitian's pay," and it had been supposed that this was the origin of the Professorship of Physic. Dr. Banks spoke at length of many of the celebrities of bygone days, and gave many interesting particulars concerning several of them. Speaking then of medical education, he urged the desirability of lengthening the medical curriculum to a period of five years, and also urged the importance of a study of mental disease. As to the question of the expediency of women entering the profession, he said he would express no opinion, but observed that there was a large field for them in India. On sitting down, hearty cheers resounded throughout the hall (the Dining Hall of Trinity College). Here an unfortunate hitch occurred. Forgetful, apparently, that it was usual to pass a vote of thanks to the President for his address, the President of the Council rose to give out some notices of other business, but was cut short suddenly by the Rev. Dr. Haughton, who is the Senior Fellow of Trinity College, and combines in his person the position of a physician and a clergyman, and is distinguished for his learning both as a mathematician and a physiologist. In a speech, marked throughout by great humor, he said he rose to move the adjournment of the debate in order to call attention to a matter of urgent public business, and then said that, although he did it that should not, he must move a vote of thanks to Dr. Banks. He agreed with him in everything but one—his admiration of women. Dr. Banks wished them to practise in India. He wished them to practise in Ireland, not "far, far away"—the last phrase being sung out at high pitch, in what a member who sat near me remarked was an imitation of Professor Blackie's manner. The vote of thanks was afterward formally moved and seconded in the usual way, by Sir George Paget and Sir Spencer Wells, respectively.

On Tuesday we had Professor Gairdner's Address in Medicine. After a few introductory remarks, he referred to the question mockingly asked by Sir William Hamilton in a review of Cullen's works: "Has the *practice* of medicine made a single step since Hippocrates?" Dr. Gairdner remarked that he had chosen a less ambitious programme, viz., to inquire whether the art of medicine had advanced during the present century. Adopting Cullen as the starting-point, he referred to his fame. He then went on to speak of Brunonianism, of which Dr. Gairdner said he had once met a disciple. It was in the great hospital at Milan, in 1852. This Italian physician bled about every third or fourth patient, and did not use, or seem to think of using, the stethoscope. Dr. Gairdner said, that at the same hospital, at the date mentioned, he was informed that there was to be seen in the venereal wards a man who had been bled for gonorrhœa. The practice of freely bleeding as practised in the last generation was then graphically described and commented on by Dr. Gairdner. The medical art was unstable in Cullen's time. Had we attained to greater stability now? His answer was that the progress of medicine, since Cullen's time, had been in the direction of *stability* of a kind and degree not possessed by the art of medicine in any previous stage of its progress, not even in those dark ages when it had the prestige of a kind of immutability, or, as a theologian would call it, orthodoxy, founded on the overwhelming authority of Galen. Dr. Gairdner then said, could he make good this assertion? Even for antisepticism, he said he could not claim an advance all along the line. He then referred in succession to antipyretics—cod-liver oil, chloral, digitalis, nitrites, etc.—and their advantages, but said it was vain to expect a concurrence of opinion. There were three points of our progress in which the dissolution or weakening of our orthodoxies had been accompanied by a truly constructive process.

1. Hygienic remedies. Under this heading the progress of preventive medicine was spoken of.

2. Self-healing processes in acute disease. In connec-

tion with this subject, Dr. Gairdner spoke of the abuses of venesection in former years.

3. Epidemic fevers, and the reaction against over-alcoholic stimulation in treating them. Some striking reminiscences of the alcoholic methods of treatment were given. In concluding his remarks on this subject, Dr. Gairdner referred to the fact that milk had almost been forgotten in the era of which he spoke, and alluded to the epigrammatic motto of the University of Dublin, "Lacte, non Vino."

After the usual vote of thanks, a discussion then took place on a resolution moved by Sir Thomas Crawford, respecting the disabilities under which candidates with Scotch or Irish degrees or diplomas suffered when competing for English appointments. After being amended in a direction indicated by Dr. Haughton, the resolution was finally—after a wordy war of some duration—passed by an overwhelming majority.

THE JAUNDICED HUE OF PICRATE OF AMMONIA.

To the Editor of The Medical Record.

Sir: A correspondent, Dr. S. E. Fuller, of Brooklyn, calls attention to this phenomenon in your July 2d number.

I have observed it both in sclerotics and in urine, but not so persistent or marked in my cases as appeared in Dr. Fuller's. All of my cases, having some neurotic trouble and the indications for the ammonia picrate being only incidental, were taking hypophosphites and ammonium bromide, and some iodide and arsenic. In those patients who happened to be taking muriate of ammonia with other treatment, the yellow tinge to urine and sclerotics appeared very slight, and in some not at all; and in all, the subsequent administration of the ammonium muriate and suspension of the ammonium picrate cleared away the jaundiced hue in a few days.

There was no cutaneous icterus in any of my cases.

I attributed the change to the diffusion of the coloring matter of the picrate of ammonium through the tissues, as urinary examination showed nothing abnormal, and made this explanation (and still make it, when I use this salt) of this discoloration-phenomenon.

Yours truly,

C. H. Hughes.

3000 Chestnut Street, St. Louis.

SOLID TUMORS OF THE OVARY.

To the Editor of The Medical Record.

Sir: I notice in The Medical Record of July 9th a note from Mr. Lawson Tait in regard to a report of a quotation made by me from his book. As Mr. Tait suggests, I have not been correctly reported. I quoted from his book (p. 158) the following: "Growth of the fibrous stroma of the ovary so far as to form a large abdominal tumor requiring removal has not yet been described." I then asserted that in this statement Mr. Tait is wrong, and this I still maintain. That Mr. Tait's position on this subject may be fully understood, I quote again from a private communication of July 2d, in which, in speaking of solid ovarian tumors, he says: "A purely fibrous tumor in which the follicular element does not enter has yet to be described. I said so in 1877, and I say so again." In my paper (*Am. Jour. of Obstet.*, vol. xx., May, 1887), from the report of which Mr. Tait quotes, I described a purely fibrous tumor of the ovary in which there was no trace of follicular structure. Many others have done the same.

In a paper by Dr. Coe (*Am. Jour. of Obstet*, vol. xv., p. 561) the whole subject is fully discussed, and reference made to a large number of reported cases. I need only allude to the latest authority, Dr. Greig Smith. In his work on "Abdominal Surgery," after quoting from Mr. Tait the very sentence which I have used, he goes on to describe a tumor of the kind the existence of which Mr. Tait denies. He says: "I have, however, successfully removed a solid ovarian tumor as large as a child's head, in which repeated examinations by a competent histologist failed to show any other histological element than pure fibrous tissue." Certainly this would seem to be conclusive.

Matthew D. Mann, M.D.

Buffalo, July 18, 1887.

A LAYMAN'S OBJECTION TO MEATOTOMY.

To the Editor of The Medical Record.

Sir: Is it scientific for a surgeon to advise a layman to undergo an operation for which there is no published authority and of which the only papers written by physicians are condemnatory? Enlarging the meatus to the calibre of the urethra seems to be such an operation. I am told that it is frequently performed by genito-urinary surgeons; and I have, indeed, read a book, by one of them, wherein mention is made of more than a thousand urethral operations, in each of which the meatus was enlarged, simply to make way for the passage of instruments; but, for aught the text says, with no idea that the enlargement would have in itself any more effect than would be produced by paring the patient's finger-nails. It would be interesting to know whether many of the men whose meati were thus cut find that, in consequence, they are rendered impotent, unable to urinate without wetting themselves, and dribblers for a long time after urinating; because these are the results which the only physicians who have written on the subject say are likely to be produced by *porotomy*. One of these writers even cites a number of instances in which he has removed the difficulties mentioned, by sewing up the meatus so as to bring it to its normal size. Think of it! One member of a medical society takes a fee for cutting a patient, and another member receives a fee for bringing the patient as nearly as possible back to his original condition.

In *my* profession, if a small number of, say, bridge-designers, were to proportion their framed structures in a manner which other well-known engineers say, in published papers, is likely to make the structures insecure, it would be considered that the persons who pay for the structures have a right to expect that the designers will point to some scientific evidence that the criticisms are unmerited. An engineer, indeed, must either defend his practices against criticism from responsible sources or else lose the confidence of the persons who employ him. Not so, it seems, with genito-urinary surgeons. No matter how many papers are written by prominent physicians to show that permanent enlargement of the meatus is an unscientific, injurious operation, the genito-urinary surgeons go on complacently performing the operation, and never answer a word.

I would say to any physician who makes a practice of enlarging the meatus: "The opportunity is afforded you of being the pioneer in disproving the proposition advanced by several prominent practitioners, that the operation is injurious to the patient. It may take some nerve for you to express in print the conviction that the operation is beneficial; because many of the men whose meati have been enlarged may perhaps rise up and bear witness against you. Still, I submit for your consideration that for any surgeon to perform an operation which he is afraid publicly to defend is mean and dishonorable."

A Civil Engineer.

New York, July 29, 1887.

A Plea for More Frequent Phlebotomy.—In an article in the July issue of the *American Journal of the Medical Sciences*, Dr. J. A. Macdougall urges the more frequent employment of bloodletting as a therapeutic measure. He believes that it is too much neglected at the present time, and that its occasional employment in suitable cases is productive of undoubted good.

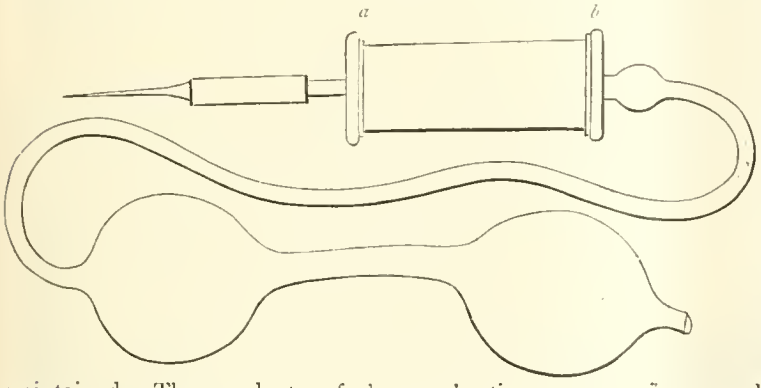
New Instruments.

AN IMPROVED FORM OF PAQUELIN CAUTERY.

By HORACE B. SCOTT, A.M., M.D.,

ASSISTANT SURGEON, UNITED STATES NAVY.

The action of the Paquelin thermo cautery, as commonly used, may be briefly stated as follows: Air is forced into a bottle containing benzole; thence, after becoming saturated with the vapor, it is driven on into the knife until it reaches the platinum tip, which, having been previously heated, is kept at an incandescent temperature by the combustion of the vapor striking against its inner surface, so long as the current of air, charged with the vapor, is



maintained. The products of the combustion escape backward along the delivery tube and out through vents made for the purpose.

A glance at the accompanying illustration will show the modifications suggested, and claimed as improvements. The handle in the ordinary form of the cautery is merely a piece of wood with a tube passing through it. In the modified apparatus the handle is a nickel-plated brass cylinder, filled with sponge confined in a spiral of brass wire. It is both a handle and a chamber, in which the air becomes saturated with the benzole vapor as it passes through on its way to the knife.

The points in favor of this handle are: 1. Efficacy. The air is more easily and thoroughly saturated with the hydro-carbon vapor, so ordinary benzine can be used instead of the more expensive and more volatile benzole. 2. Safety. There is no possibility of the benzine chamber breaking or of the cork blowing out, as obtains sometimes when the bottle is used. 3. Convenience. It does away with a bottle hanging from a button-hole, and with the extra length of tubing for connections which is, at times, in the way. It cannot be upset. A much smaller quantity of benzine will suffice to impregnate the air with vapor than when only the surface of the liquid is exposed to volatilization, as is the case when a bottle is used. Lastly, there are fewer pieces needed.

Mode of using: Unscrew one end of the cylinder and pour a little benzine on the sponge within; replace the end, and the instrument is ready for use. It can be transported any distance, as there is no leakage nor waste, both ends being made tight by little screw-plugs, which fit in where the tubes from the bulbs and to the knife are connected (see figure, *a* and *b*). Once filled, it can be used continuously for at least two hours, and probably longer, as I have used it that length of time, and it was not then exhausted. The above description is that of an instrument made, after plans by the writer, on board the U. S. S. Trenton, then off Yokohama, Japan. The credit of originality is due to Stuart Eldridge, M.D., of Yokohama, who had an instrument differing from the above in only one or two minor details, and made before the one here described.

EMPYEMA STOPCOCK.

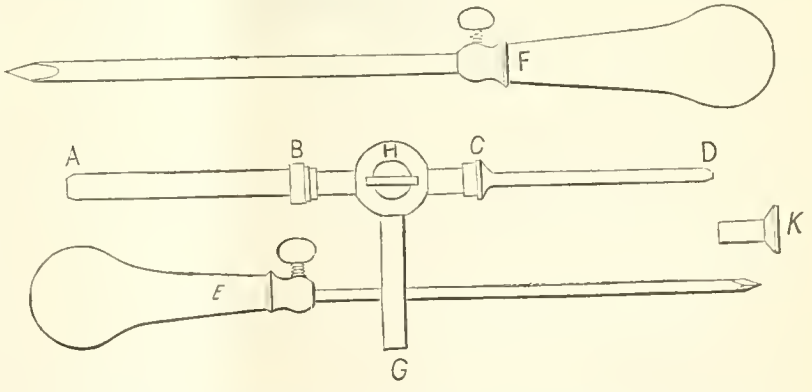
By HORACE B. SCOTT, A.M., M.D.,

ASSISTANT SURGEON, U. S. NAVY.

The combined stopcock, trocar, and cannula here described was designed for a special case, but the writer found it so convenient that he believes it will prove useful in other cases as well. In its simplest form the instrument may be described as a three-way cock, so arranged that fluid will pass from the syringe or reservoir into the chest when the stopcock is horizontal, while by turning it in a vertical direction the fluid flows from the thoracic cavity into a receptacle placed to receive it. When the stopcock is in this latter position further entrance of fluid into the chest is prevented. The accompanying figure represents this instrument adjusted for use with two trocars of different sizes. By unscrewing the cannula, *CD*, the larger trochar, *F*, will pass from *C* to *A* through the stopcock, *H*, and by removing the cannula, *AB*, the smaller trochar, *E*, will pass from *B* through the stopcock to *D*.

Both trocars, *F* and *E*, have a set screw in the handle by which the spear can be set in far enough to use it and its corresponding cannula, *AB* or *CD*, separate from the rest of the instrument—in fact, like an ordinary trocar and cannula—and it is for this purpose that two sizes are adapted in the instrument. *K* is a small plug to fit at *B* after the removal of *AB*; through it is a hole of the same size as the smaller trocar, *E*; it is a guide to be used only when the trocar is used at full length.

Connection is made at either end with the syringe or reservoir by rubber tubing, while from the other end is another tube (catheter) reaching to the bottom of the cavity to be washed out. The surgeon, with his hand on the stopcock, *H*, can check the in-flow and open the out-flow at any instant he may wish.



Though perhaps somewhat complicated in description, the instrument itself is quite simple, easily cleansed, and has been found very convenient by the writer. Empyema only has been mentioned as a disease in which it is useful, but it can be equally well used in all diseases requiring the trocar and cannula, either by using the trocar and cannula alone, or, in the combined instrument, withdrawing the trocar partially, turning the stopcock, and allowing the fluid to run through the outlet-tube, *G*. If desired to leave a drainage-tube in the cavity, it can easily be passed through the cannula before it is withdrawn.

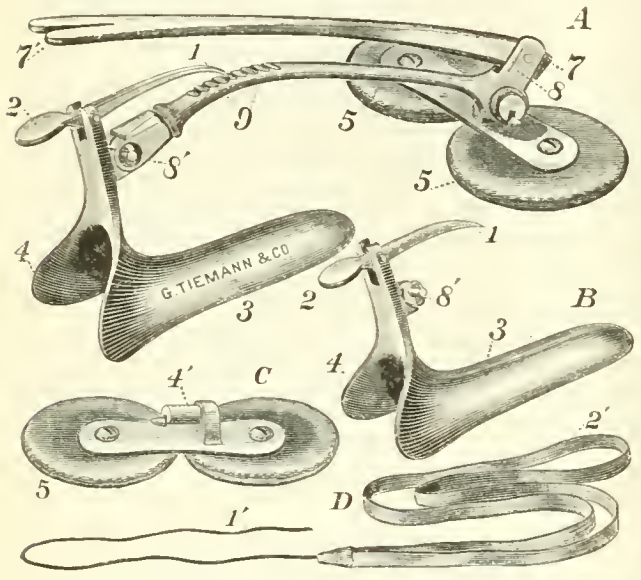
The Medical Societies will resume business next month.

AN IMPROVED EHRICH'S SELF-RETAINING SPECULUM.

By H. T. HANKS, M.D.,

NEW YORK.

Any self-retaining speculum which will do the work of a Sims' speculum, even *fairly* well, is certainly a very desirable instrument, even though its use may be somewhat limited. I have had opportunity and have taken occasion to use nearly every kind of these instruments which are for sale, and I have found none that served me so well as an Ehrich, or some modification of the Ehrich, self-retaining speculum. It is well known that Dr. A. H. Hunter and Dr. B. F. Dawson, of this city, each have made decided improvements in this instrument, and I presume other improvements have been suggested by gynecologists in other parts of the country. I have found, however, that there were some changes which could be made which would in a great measure remedy the defects which have always been present in the original, and in the several improvements which have been from time to time recommended by me and others. And that the general profession may know of a really useful self-retaining instrument I venture to describe the Ehrich speculum as improved and used by me.



1. In Fig. "A" the arm 8–8', which is the short arm of the lever, is one inch shorter than is found in the original instruments, and therefore the perineum is retracted with greater ease, and when it is remembered the patient is to make the traction which is to accomplish this purpose, it is seen to be quite an advantage.

2. The distance of the blade 3, in Fig. "A," from the short arm 8–8' is one-third of an inch more than in the original instrument, and we thus avoid the danger which was always present in the old speculum of puncturing the tissue around the coccyx and perineum.

3. The attachment, in Fig. "A," of the short arm 8–8' to the blade, at 8', is similar to the attachment of disjointing scissors. And thus the blade can be removed instantaneously from the arm 8–8', and washed, without wetting the other parts of the speculum.

4. The ratchet 1–2', in Fig. "A," is easily and quickly manipulated. The end at 2 is arranged to be lifted by the thumb, to retract still more the perineum.

5. The fulcrum pieces 5–5', in Fig. "A," are of metal covered with soft buckskin. They do not easily slide or slip on the integument of the parts around the sacrum, and of course they do not chill the patient.

6. The long arm of the lever 7–7', in Fig. "A," is made strong, and stands. when in use, at nearly a right angle to the short arm 8–8'. At the end 7'; a wedge-shaped slat is made for catching firmly the tape- or leather string which is held by the patient.

7. Two different-sized blades are made and sold with this instrument, and others can easily be made to suit the fancy of the owner.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 7 to August 13, 1887.

McKee, J. C., Major and Surgeon. Ordered for duty at Watertown Arsenal, Mass. S. O. 181, A. G. O., August 6, 1887.

Brown, H. E., Major and Surgeon. Sick-leave extended to August 6, 1887, on account of sickness. S. O. 184, A. G. O., August 10, 1887.

Cleary, P. J. A., Major and Surgeon. Ordered to Fort McDowell, A. T., instead of Fort Assiniboin, Mon. Ter. S. O. 180, A. G. O., August 5, 1887.

Dickson, John M., Captain and Assistant Surgeon. Died, August 8, 1887 (station, Fort Mason, Cal.).

Merrill, J. C., Captain and Assistant Surgeon. Ordered from Fort Klamath, Ore., to Watervliet Arsenal, N. Y. S. O. 181, A. G. O., August 6, 1887.

Macauley, C. N. B., First Lieutenant and Assistant Surgeon. Promoted to be Assistant Surgeon with the rank of Captain by operation of law. August 10, 1887.

Hopkins, William E., First Lieutenant and Assistant Surgeon. Ordered from Angel Island, Cal., to Fort Mason, Cal. S. O. 184, A. G. O., August 10, 1887.

Pilcher, J. E., First Lieutenant and Assistant Surgeon. Ordered from Fort Monroe, Va., to Fort Wood, N. Y. Harbor. S. O. 180, A. G. O., August 5, 1887.

Anderson, C. L. G., First Lieutenant and Assistant Surgeon (station, Whipple Barracks, Ariz. Ter.). Ordered to Fort McDowell, Ariz. Ter. S. O. 81, Department of Arizona, August 3, 1887.

Suter, William N., First Lieutenant and Assistant Surgeon. Ordered to return to Washington Barracks, D. C., on the breaking up of the camp at Creedmoor, N. Y. S. O. 166, Division of the Atlantic, August 10, 1887.

Action of the Liver on Poisons.—Dr. Roger has published the results of his researches on the action of the liver on poisons. Having verified and confirmed the assertions of Heger and Schiff on the modifications which the alkaloids underdo in the hepatic parenchyma (*The Lancet*), Roger shows that the liver transforms also the normal poisons of the organism, including both the products of disassimilation and the toxic principles which arise from intestinal fermentation. The most interesting and novel point is that the action of the liver on organic poisons only takes place in the presence of glycogen. This is established clearly in the different experimental diseases of the liver, particularly in animals in a state of inanition, where the gradual and parallel decrease in the two functions can be followed day by day. On the other hand, when hyperæmia of the liver is artificially induced by the injection of irritants into the vena porta, both functions are exaggerated; more glycogen is present and a larger quantity of poison is transformed. Roger thinks that the glycogen, changed into glycose, combines with the alkaloids, or with ammonia, to form new and less toxic products, such as he has obtained, outside the body, by heating mixtures of glycogen with alkaloids or ammonia in closed tubes. These experiments lead to various clinical deductions, which are reserved for a future memoir.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and death from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 13, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	40	9
Scarlet fever	28	6
Cerebro-spinal meningitis	5	5
Measles	18	2
Diphtheria	81	29
Small-pox	1	2
Yellow fever	0	0
Cholera	0	0

REVOLVER-BULLETS IN THE BRAIN.—Dr. Berra has published a paper on penetrating wound of the brain by a revolver-ball. A man received a shot in the head from a revolver; the bullet entered the brain and blood flowed from the nose. Symptoms of cerebro-meningitis followed and the foreign body could be distinctly felt by the probe through the wound. The man made a perfect recovery. Verneuil said he knew two men who each had a bullet in the brain, and were now in the best of health. Sée mentioned two similar cases. Dentu related the following case: A man received a ball in the forehead; vomiting, difficulty in speaking, and brachial monoplegia were the primary results. At the end of two months symptoms of abscess of the brain were manifested, and the use of the trepan was suggested, but abandoned. The man died and the autopsy revealed an extensive suppuration, but, strange to say, the ball was lodged in a cyst and at a certain distance from the abscess. Peyrol said that active interference was justified in such cases, especially as very little danger resulted. Kirmisson was of opinion that a primitive exploration was not correct practice, and he was struck by the history already related, that certain fractures of the skull provoked suppuration, without injury to the teguments. In such cases he considered that the inlet of the microbe of pus was through the ear, especially in cases of fracture of the petrous portion, and consequently he placed iodoformed cotton in the auditory canal, and since he adopted this practice he never met with such accidents in that kind of fractures.—Paris correspondent of the *Medical Press*.

THE TREATMENT OF PAIN BY ANTIPYRIN.—Professor Germain Sée has made a further communication to the Academy of Sciences on the treatment of pain by antipyrin (*The Lancet*). He now advises that the drug be administered by hypodermic injection in doses of eight grains in the same quantity of water. The injection is followed by a disagreeable feeling of tension which lasts a few seconds; and, when this passes off, the pain, whatever may be its cause, at once remits. It has the great advantage over morphine of giving rise neither to vertigo nor vomiting; nor does it produce either the somnolence or the artificial stimulus which lead to morphinomania. Lastly—and this is the great point—to its sedative effect it adds a curative action, which morphia does not possess. The diseases for which Professor Sée would more especially recommend the substitution of antipyrin for morphine are numerous—acute rheumatism, acute gout, herpes zoster, lumbago, ataxia; also in hepatic and nephritic colic, angina pectoris, and acute asthma. "But there is no morbid condition in which it does not advantageously replace morphia; and as we gather experience we shall see antipyrin used in its stead, and so become the preservative against chronic morphia poisoning."

NASAL VERTIGO.—The thesis might be maintained that irritation of any sensory area may give rise to vertigo; but the difficulty of proving to demonstration that such a proposition holds good would be very great. Hitherto the occurrence of vertigo as the result of a lesion in the nasal passages has not been generally accepted, and we doubt whether there can be any very special or causal connection between a vertigo and a nasal lesion. In a few cases a connection may be traced, but it is very possible that the nervous phenomenon, vertigo, is chiefly caused by the nerve weakness, the nasal lesion playing perhaps only the part of the "last straw." Dr. Joal, the latest writer on nasal vertigo, believing in its positive existence, asserts that the vertigo is a genuine reflex; that it ought to be ranged side by side with gastric, laryngeal, uterine (*sic*) forms; and that irritation of the branches of the trigeminal supplying the mucous membrane of the walls and septum of the nose is its cause. He thinks that the mechanism is one of cerebral anæmia brought about by the transmission of the irritation through the spheno-palatine ganglion to the vaso-motor nerves. The vertigo is especially induced by slight nasal affections such as result from inhalation of irritating vapors, snuff, etc. Acute coryza, hypertrophic chronic catarrh, mucous polypi, and catarrh of the retro-pharynx are other causes. These reflex effects are most marked in arthritic subjects. The vertigo may be the only symptom, or it may be accompanied by visual troubles, hemicrania, nausea, vomiting, great excitement, hypochondria, intellectual weakness, etc. The statement is also made that the vertigo ceases with the cure of the nasal affection which has caused it.—*The Lancet*.

SOME QUERIES CONCERNING BERGEON'S TREATMENT OF PHTHISIS.—Dr. George White, of Chicago, asks the following questions: "1. Does sulphur have, under all circumstances, an elective affinity for the respiratory tract, such as some remedies have for other organs? 2. Does hydric sulphide vary in quantity in the digestive tract during the progress of phthisis, as sodic chloride fluctuates in the urine of patients with pneumonia? 3. During the phthisical processes is there a deficiency or absence of any of the bile constituents, such as the taurocholate of sodium? 4. In consumptive patients does the discharge of gas from the rectum vary in quantity and odor as the disease progresses or retrogrades? 5. Do not the good effects of injections of hydric sulphide per rectum show a want of the sulphur element in the human economy? 6. If these things are true, may we not supply the deficiency by such diet as will be as sulphurous as can be tolerated by all parts of the digestive apparatus; such, for example, as yolks of eggs, ox-bile, beans, or sulphuric-acid lemonade? Queries 1 and 3 I shall hope to see answered by those more competent than myself; queries 2 and 4 I am endeavoring to solve; No. 5 appears to be self-evident; No. 6 remains to be proven. A partial tour of the Cook County and Presbyterian Hospitals, in Chicago, has given me a little foundation for my belief that affirmative replies may be made to queries 2 and 4. There is great difficulty in gaining any satisfactory information from the average patient, but what little information I obtained I here impart. In two cases the testimony was positive that, as the cough and prostration increased, the intestinal odors decreased or ceased, and when there was improvement in the general condition the fecal matters grew more offensive in smell. In one case the testimony was exactly the reverse of this. I intend to investigate this subject further, and trust that some readers of THE MEDICAL RECORD will accurately answer my other questions. This is an immediately practical subject."

LATE DENTITION.—Dr. Dolgopoloff saw a curious case of an elderly but still hale and sound nurse, aged sixty-eight, who had long before lost all her teeth except four lower incisors, and in whom two new upper middle incisors appeared, first the right one (at sixty-seven), and about a year later the left. On both occasions the dentition was accompanied by severe headache, loss of appetite, vomiting, diarrhœa, slight febrile movements with

shiverings, rapid action of the pulse, and aching and dragging sensation in the gum. While her old teeth were dark gray, the new ones had a milky color with a bluish tint; they were competent even for such work as biting sugar. Dr. Dolgopoloff emphatically draws attention to the fact that dentition in his patient was accompanied by a set of symptoms which obviously had a reflex origin, and which are only too well known in cases of teething at a somewhat earlier age, though some sceptic minds attempt to explain away those irritation-phenomena by a simple coincidence of events.

Louis XIV. and His Dose of Cinchona.—Dr. J. H. Straughn, of Lexington, Mo., writes: "Voltaire, in his work entitled 'Le Siècle de Louis XIV,' relates the following interesting anecdote: In the year 1658 the king was seized with a severe illness at Calais, and for several days was in imminent danger of dying, but was cured by an empiric of Abbeyville with 'un vin hémétic,' which the court physician regarded as a poison. This good man (the empiric) sat down on the king's bed and said, 'Here is a young man very ill, but he shall not die.' And the prognosis was verified. May we not reasonably infer that this medicine was a vinous preparation of cinchona bark, which we are told was introduced into Europe in the year 1640?"

Large Doses of Quinine.—Referring to the claim of Dr. Knight, of Dublin, that the largest dose of quinine ever given was by himself, the amount being 131.25 grains in twenty-four hours, a correspondent calls his attention to the statement in "Stille's Therapeutics," vol. i., p. 497, edition of 1860, that a lady took about ten drachms in a few hours, a man took five hundred and ten grains in seventeen hours, and another took four hundred and eighty grains in a single night.

The Treatment of Localized Tuberculosis.—In a recent number of the *Mediz. Presse*, Dr. Kolischer gives details of his new method, and Dr. Freund describes the composition of the solutions used. In the case of tubercular masses which have not yet broken down, the following is the plan adopted: After a sublimate dressing had been applied to the part for twenty-four hours, this was again washed with soap and irrigated with a one per cent. solution of sublimate; after this the injections were made. For this purpose he used a Pravaz syringe, made of vulcanite, with platinum points. The syringe was dipped in a five per cent. solution of carbolic acid. The injection was made slowly at different points of the mass, a portion of the contents of the syringe being injected at each place. When a sufficient quantity of the solution had been injected, the fungous mass felt soft, whereas the parts where no injection had been made were elastic to the touch. The needle was pushed in as far as possible, sometimes even to the softened bone. When healthy tissue was reached, a peculiar quivering sensation was felt, which was absent when the point was in the diseased mass. Moreover, there was no bleeding after puncture of a tubercular mass. The injection itself is so painful that cocaine might advantageously be used at the same time. Very severe pain also comes on some time after the injection, and lasts for some hours; this is best relieved by subcutaneous injection of a somewhat large dose of morphine. After the injection of the lime salts, an antiseptic dressing should be at once applied, and should be left on during the whole period of reaction. The reaction-fever is usually very high, and lasts from twelve to twenty-four hours. When the reaction—which usually lasts for five or six days—subsides, a starch-bandage should be applied to the joint, and this should be changed as often as it becomes loosened by the swelling which supervenes in the joint. Then, after a period of from three to six weeks, the stage of induration, shrinking, and absolute painlessness is attained, massage and passive movements should be had recourse to, in order to restore the mobility of the joint. The subluxations and contractions which may have been produced in the course of the disease should be corrected toward the end of the period of reaction. When the mass into which an injection was made was gradually undergoing caseation, it broke down after about a week, and tubercular granulations, fibrinous clots, and flakes of pus were discharged. The cavities were stuffed with the prepared gauze, and the whole was covered with a sublimate wood-wool dressing. The tampons should be changed at least every second day. The cavities, under this treatment, quickly became covered with healthy granulations; and, when these had reached the surface, the usual treatment of granulating surfaces with nitrate of silver and iodoform was employed. Cold abscesses were opened as freely as possible, and, after emptying out the contents (without using the sharp spoon), they were stuffed with gauze saturated with the phosphate of lime solution. When the ulcerative process was very indolent, gauze prepared with the stronger solution was used. With respect to lymphomata which had not yet broken down, the number of experiments which had hitherto been performed was too small to justify a definite conclusion. The solutions should be prepared according to the following formulæ, suggested by Dr. Freund: 1. Acid solution of phospate of lime of about 6.5 per cent., containing 1 in 1,000 of free phosphoric acid (sterilized for injection).—℞. Calc. phosph. neutr., 5.0; aq. destill., 50.0. Dein sensim adde acid. phosphor. quantum sufficit ad solutionem perfectam; filtra, et adde acid. phosphor. dil., 0.6; aq. destill., q. s. ad 100.0. S.: For injection. 2. Acid solution of phosphate of lime of about 6.5 per cent., containing 1 per cent. (or 2 per cent. when the ulcerative process is particularly indolent) of free phosphoric acid, for impregnation of the gauze.—℞. Calc. phosph. neutr., 50.0; aq. destill., 500.0. Dein sensim adde acid. phosphor. q. s. ad solutionem perfectam, filtra, et adde acid. phosphor., dil., 60.0 (vel 120.0); aq. destill., q. s. ad 1,000.0. S.: For impregnation of the gauze. The solutions were thoroughly sterilized each time before being used.—*Cor. British Medical Journal.*

An Itinerant Dispensary.—Dr. Bejan, of Bucharest, is conducting a travelling hospital and dispensary in Roumania, which seems to be of a very useful character. Physicians are scarce in the country-districts there, and the aim of this expedition is not only to attend to those who may be in need of medical assistance at the time, but also to give such instruction in hygiene and sanitary matters as may be useful to the inhabitants in enabling them to avoid some of the preventable diseases. The expedition is organized on a military basis. During the three summer months of last year the dispensary travelled through the districts of Dorohoi and Botosani, and treated about nine thousand patients. It was proposed to continue the work this summer, visiting other districts that could not be reached last year.

Treatment of Uterine Fibroids.—Dr. Good, of Paris, writes: "In The Medical Record of June 4, 1887, you notice editorially an article on the treatment of fibroid tumors of the uterus, as practised by Dr. Martin, of Chicago, after the method of Dr. Apostoli, of Paris. Allow me to say that the 'conclusions reached by Dr. Martin,' given as his own, are substantially a translation of the conclusions published as far back as 1884 by Dr. Apostoli, in his work 'Du Traitement Électrique des Tumeurs Fibreuses de l'Utérus,' page 246. If it is not asking too much, I beg to have the error corrected."

Needles in the Heart.—At the last German Surgical Congress, Dr. Steltzner related the case of a man who had thrust a needle into his heart, with suicidal intent. A loud murmur could be heard, and the puncture made by the needle in the chest-wall was plainly visible. An incision was made at that point, and the fifth rib was resected, when the needle was seen embedded in the

cardiac wall. In the attempt to extract it the needle slipped away and could not be found. The patient recovered completely. At the same meeting Dr. Hahn showed a piece of a needle which he had removed from the heart of a child in 1882. While the foreign body remained in the heart, a loud systolic murmur was audible. The needle was extracted slowly without accident. After its removal the temperature fell and the pulse, which had before been very rapid, was much reduced in frequency. That the needle was in the heart was evidenced by its rhythmical movements corresponding in time with those of the heart.

Antifungine.—This is the name given to a white, sweetish-tasting powder, consisting of borate of magnesia prepared by a special process, and said to be an energetic disinfectant, being recommended especially in diphtheria, in which an almost specific action is claimed for it. It is employed in a fifteen per cent. solution, of which from five to twenty drops are exhibited every half-hour. In addition, in cases of diphtheria a spray of the solution is diffused through the atmosphere of the room. The solution is also applied directly to the diphtheritic pseudo-membrane by means of a soft brush.

Staining of the Urine by Picrate of Ammonia.—Dr. J. B. Wainright, of Manasquan, N. J., writes: "In answer to the inquiry of Dr. S. E. Fuller as to how long after the discontinuance of picrate of ammonium the urine will remain yellow, I would like to refer him to my article on 'Picrate of Ammonium,' published in The Medical Record for January 22, 1881, vol. xix., No. 4."

Bacteriology.—An elaborate paper on the study of bacteria by means of cultivation, with a full description of the technique, by Mr. Watson Cheyne, appears in the *American Journal of the Medical Sciences* for July, 1887. In addition to the study of culture-experiments, the author describes the technique of the method of study of bacteria in relation to the living body.

Sarcoma following Local Injury.—On May 21, 1886, Dr. Pettit was called to see a girl, aged fourteen, in good health, of German descent, who was suffering from tenderness and swelling on the outer side of the right knee consequent on a fall which had occurred about a fortnight before (*London Medical Record*). The symptoms passed off, but in about ten days returned at seat of injury, and grew worse daily. No history of syphilis could be obtained, but her father had twice been operated upon for epithelioma. As the pain and swelling continued to get worse in spite of local and constitutional treatment, and as there was an obscure sense of fluctuation, on June 12th he punctured the part with a bistoury, but only blood came away. On examination with a probe he detected a small spicula of bone in the cavity, and decided caries of the upper and outer surface of the tibia. The next day there was constitutional disturbance and fever, and all the symptoms seemed aggravated. A consultation was held with Dr. Pratt, and at his suggestion chloroform was given and the cavity was thoroughly explored, extensive caries of the tibia being discovered. A portion of the neighboring tissue was secured and examined microscopically, when it was found to be a large-celled sarcoma. Under the circumstances amputation of the leg above the knee was advised, but this was declined by the parents, and the patient died, after much suffering, about two and a half months after the local injury was sustained.

The Use of Increasing Doses of Drugs.—Dr. Gingeot says that active drugs are often toxic substances, the hurtful qualities of which are modified by suitable dosage. In considering the question of the employment of medicinal agents, it is necessary at once to note that a whole category of drugs never establish tolerance. They belong to the class of drugs the action of which is purely or principally chemical, such as the acids. On the other hand, the toxic dose of drugs which act by modifying the vital properties of tissues or organs, particularly of the nervous system, varies according to whether the dose is given at once or has been gradually reached. This being the case, it is easy to understand that certain drugs, if used for a length of time without any increase in the dose, finish by becoming positively inert. Medicine is of no importance, said Trousseau; medication is everything—an aphorism which he justified by quoting the fact that belladonna, useful in the treatment of epilepsy, is only so on condition of being given in properly increased doses. This rule may be extended to the therapeutics of various morbid conditions. In certain affections, such as neuralgia, for example, the doses should be rapidly augmented, because the malady is one of short duration, while in others the increase should be gradual so as to allow of its being maintained over a long period of time. The principle in both cases is the same. There is a group of diseases in which it would seem, at first sight, that this principle is inapplicable. Take, for instance, the case of a patient who is taking digitalis for functional derangement of the heart, dependent or not upon organic lesions. In such cases not only should the dose not be increased, but the treatment must be suspended from time to time even in the absence of symptoms of intolerance. The contradiction is only apparent, however. The reason for acting thus with digitalis is because digitalis is eminently a cumulative drug, and consequently, by giving every day the same dose, in reality the dose, measured by its effects, is being daily increased.—*Revue génér. de Thérapie.*

Foreign Body in the Face.—Dr. Bérenger-Féraud reports a remarkable case in the *Bulletin Général de Thérapeutique* of June 30, 1887. The patient, a man twenty-six years of age, had received a stab wound in the left temple nine months before being seen. He was sent to the hospital with a diagnosis of a lachrymal tumor of the right side. Examination showed the presence in this region of what was supposed to be a small foreign body. The man was anæsthetized, and a broken knife-blade, two and three-fourths inches long by five-eighths inch wide was extracted. The knife had traversed the left orbit without wounding the eye, the muscles, artery, or nerve, had crossed the nasal fossæ, and entered the right orbit, and had given no sign by which its presence could be suspected.

The Physiology of Fatigue.—Fatigue seems a simple word with a clear meaning, but how dark are the physiology and pathology of the subject is borne witness to by the elaborate researches of which it has been the centre, and the incompleteness of the solution of even its elementary problems (*The Lancet*). A thorough understanding of "fatigue" would include accurate knowledge not only of a physiological, but of a physical, chemical, and even psychological kind. Then, again, its influence as a means of treatment of disease or its effects on the already deranged organism is of interest to every medical practitioner. The most important branch of the question, however, relates to the nervous and muscular systems. In the process of getting fatigued, long before exhaustion sets in, what special parts of the neuro-muscular apparatus first become *hors de combat?* Many observers have endeavored to elucidate this vital element of the question. Some of the latest consider the weakest link to be the peripheral apparatus, and the best researches at least support such an opinion. In his very interesting papers on "Writers' Cramp and Allied Affections," contributed to the "Royal Medical and Chirurgical Transactions," Dr. G. V. Poore has brought forward many facts connected with the living human body tending to support the hypothesis which locates the mischief in such cases to the peripheral apparatus. The experimental evidence adduced by Dr. Augustus Waller is confirmatory of such a view, and, besides, is of a highly suggestive character. It is difficult to assign adequate reasons for the notion, but *a priori* we should expect

that the points of junction of any apparatus would prove the weakest parts thereof. And so it apparently is in the neuro-muscular apparatus. The weakness appears to exist neither in the nerve cell of the motor cortex, nor perhaps even in the motor cell of the spinal cord, nor farther down in the muscle itself, but rather in the junction between the pyramidal fibres and the motor cell of the cord and the similar place (the motor end-plate) in the muscle. An analogy between these two sites has been clearly drawn by Dr. Gowers, who pertinently suggests that some agencies—disease as well as drugs—may paralyze the terminations of the pyramidal tracts in a similar way that curare, and perhaps other agents or agencies, destroy the function of the motor-end plate. Another important point to be decided before we can be fairly considered to have any real knowledge of the nature of fatigue is the causation of the nutrition of these terminal organs—the actual conditions on which they depend for their existence as functional elements. All the information at present at our command would seem to show that the periphery is at the mercy of the centres; that the central motor cells can live and have their being without the aid of the terminal ramifications. And the evidence appears altogether opposed to the belief that any "mutual tension" exists between centre and periphery, though such a belief is entertained by Dr. Broadbent and others. Easy as the matter seems of experimental demonstration, a further consideration clearly shows the vast difficulties in the way of settling even the simplest points in the problem. Dr. Waller thinks there is evidence of a trustworthy character tending to prove that the nerve-trunk lasts longer than the motor end-plate; that repeated stimulation of the latter causes its functional death before the disappearance of the function of excitability of the nerve. In the nature of things, a definite proof of this problem could only be ascertained by the employment of delicate instruments of research, whose indications, though accurate so far as they go, are yet liable to errors of interpretation. A deflection of the needle may be significant of the passage of a genuine impulse along the nerve which forms part of the circuit—the true negative variation; but accidental currents may cause confusion, and the phenomena attending the electro-tonic state are not among the most simple in physiology. If matters are no better advanced in the sphere of neurology, what shall we say when we turn to the process of fatigue in other organs? Nor are the pathological manifestations sufficiently understood, a fact of which we are reminded by the work of Angelo Mosso, of Turin. He states that fatigue carried beyond the moderate stage, at which it is decidedly beneficial, subjects the blood to a decomposing process through the infiltration into it of substances which act as poisons—substances which, when injected into the circulation of healthy animals, induce malaise and all the signs of excessive exhaustion. That the chief cause of fatigue is the production of certain products and their action on the tissues is not a self-evident proposition, because it seems to be clear that any tissue excited unduly in a given space of time must become exhausted. And it is equally possible that fatigue as a sensation may be caused by the negative condition of diminished reconstruction as by the positive one of actual irritation by the products of metabolism. The facts at present ascertained would seem to prove that the negative and the positive states are both operative in the causation of fatigue.

The Action of the Diaphragm.—Dr. Hasse finds that the contraction of the muscular fibres of the diaphragm causes a flattening and descent of the diaphragmatic domes. The tendinous centre also descends, and becomes flattened by the traction exerted upon it from every side by the muscular fibres (*The Lancet*). In deep inspiration the descent of the diaphragmatic domes is always more considerable than that of the tendinous centre. The contraction of the muscular fibres of the diaphragm causes, as was maintained by Duchenne, an expansion of the lower aperture of the chest, owing to elevation of the ribs and of the sternum. When contraction of the muscular fibres of the diaphragm takes place, the muscular plane they form separates from the long walls of the thorax, and consequently cause an enlargement of the complemental space of the pleural sac; and to so much the greater extent the greater the coincident elevation of the thoracic cage. The descent of the diaphragm augments the normal positive intra-abdominal pressure, while its ascent diminishes the pressure, though never to zero. The changes of position which occur in the descent of the diaphragm cause a corresponding change in the position of the viscera lying subjacent to it—as the liver, stomach, and spleen. The liver is consequently by no means a rigid, fixed organ, but varies both in form and position. When the diaphragm contracts, the resistances to the flow of blood through the liver and spleen are overcome, and the passage of blood through them is rendered easier in proportion to the freedom of the respiratory acts. Lastly, the movements of the diaphragm are essential for the discharge of the bile, and further the movement of the contents of the stomach and intestines.

The Administration of Carbonate of Lime as a Means of Arresting the Growth of Cancerous Tumors.—Nearly twenty years ago Dr. Peter Hood published a communication on the value of carbonate of lime in the form of calcined oyster-shells, as a means of arresting the growth of cancerous tumors. In the *Lancet* (May 7, 1887) he publishes a second communication on the same subject, in which he states that although his opportunities for employing it in suitable cases have not been large, the results which he has attained through its use have been very satisfactory. He refers to several cases in which a persevering use of the calcined shell powder arrested the growth and pain in tumors undoubtedly of a cancerous character. Dr. Hood urges the persistent and fair trial of this remedy in cases of cancer, where the nature of the affection is early recognized. It can do no possible harm, it need not interfere with other remedies for the relief of pain, its action can be referred to an intelligible and probable hypothesis, and it has been of utility in a sufficient number of cases for warranting us in reposing some confidence in its use. An advantage of the treatment is that the remedy may be readily prepared at home by baking oyster-shells in an oven, and then scraping off the calcined white lining of the concave shell. The substance thus obtained is to be reduced to a powder, and as much as will lie on a silver quarter taken once or twice a day in a little warm water or tea.

Swallowing Glass.—Dr. J. C. McMillan, of Marion, S.C., reports, in the form of a reprint, the case of a child, ten months old, who had been playing on the floor where a lamp-chimney had been broken, and had swallowed some of the fragments. The mother had been in the habit of giving it pieces of ice frequently, and doubtless the infant took to eating the glass for the ice. The child was seen by the writer the day after the glass had been taken into the stomach. There seemed to be very little physical disturbance, and aside from a slight rise of temperature, 99½°, the little patient seemed to be enjoying its usual health, although it had been for two days constipated. The treatment consisted in rest, castor oil, flaxseed, and slippery elm. A few hours after the first dose of oil, the glass began to pass. A dose of oil was given every day for four days, the glass continuing to pass each day. The mother did not collect the glass on the first day, but on the three days following seventy pieces were collected, varying in size from one-fourth to three-fourths of an inch in length. After this the patient seemed to get along very nicely. Notwithstanding that part of the glass remained in the intestinal canal for six days, no symptoms of inflammation, ulceration, or obstruction occurred.

SOME POINTS IN LAPAROTOMY FOR VISCERAL INJURIES.

By T. A. McGRAW, M.D.,

DETROIT, MICH.

It is no longer necessary to urge theoretical reasons in justification of laparotomy for concealed wounds of the abdominal viscera. There are already a sufficient number of successful cases on record to establish the operation as one of recognized merit; and that which now remains to do, is to decide upon those technical details, attention to which can alone make the procedure generally successful.

In this paper I shall limit myself strictly to the study of such penetrating wounds of the abdomen as are caused by stabs, punctures, and gunshots, omitting all consideration of contused, lacerated, and incised wounds. I shall have to deal, then, only with such wounds as are distinguished by small external openings, leading into narrow channels, and which are therefore characterized by great and necessary obscurity in diagnosis. Even with these limitations the subject is one of great scope, requiring study from many stand points. The anatomy of the abdomen and its viscera must be studied with an especial view to operations for the repair of injuries. The very shape of the belly, as it changes in repose and action, may have a decided influence in determining certain practical points. The course of a bullet or weapon through the body, and the deviations of missiles from the straight line, have to be carefully studied for purposes both of diagnosis and treatment, and the symptoms caused by the various injuries of various organs demand attention. The relations of the external wound and that through the abdominal wall to the internal injuries, the place and character of the incisions to be made by the surgeon through the abdominal wall, the treatment, operative or otherwise, of the injured viscera, the methods of controlling hemorrhage, and the discrimination of cases which require operations from those in which operations are unjustifiable, are all subjects, new as yet to the profession, which give opportunity for much difference of opinion, and which, therefore, are properly open to discussion. I shall not attempt, however, to do more than to discuss a few of the very many points which would present themselves to the surgeon in relation to this subject.

We may divide the viscera of the abdomen into classes from many different stand-points. They may be divided, first of all, by their relations to the peritoneum, some being completely invested by that membrane, while others are either incompletely invested by it or lie altogether without its folds. Wounds of the one kind are marked by extravasations into the peritoneal cavity, those of the other by extravasations into the cellular tissue. We may further divide them into solid and hollow. Solid organs, when injured, may pour into the surrounding spaces their own peculiar secretions, and blood from their broken vessels. The hollow viscera may, in addition, pour into the peritoneal cavity or cellular interspaces quantities of foreign matter, which may be undergoing the changes of fermentation or decomposition. Injuries of the solid viscera may cause death by shock, by hemorrhage, by traumatic inflammations and abscesses, and by suppression of an essential secretion. The injuries of certain of the hollow organs, and especially of the alimentary canal and urinary bladder, may, in addition, cause danger from the septic organisms, which they sometimes contain in great numbers, and which are, in case of injury, let loose upon defenceless portions of the organism.

While both of these divisions are of certain practical importance, I shall nevertheless discard them in this paper for one which I consider to be of prime importance to the practical surgeon. I shall divide the abdominal viscera according to the degree of mobility which they are permitted to exercise in the abdominal cavity. We find in this respect the greatest differences in the various organs; for while some, like the ileum and jejunum, have a range of motion which permits them to be drawn to almost any point in the abdominal cavity, others, like the extra-peritoneal portions of the duodenum, are bound down to a very limited area. While no one organ can, strictly speaking, be said to be absolutely immovable, nevertheless the motion permitted to certain organs is so small as to be practically of no value. I shall therefore divide the abdominal viscera into the movable and immovable, using these terms relatively and not absolutely, and I shall hope to show, in the course of my argument, that the two classes require to be so differently considered, when made the objects of operative procedures, as to warrant this mode of classification.

The movable viscera are the spleen, pyloric ends of the stomach and duodenum, the transverse colon, the ileum and jejunum, the sigmoid flexure, and the ovaries.

The immovable viscera are the liver and gall-bladder, the kidneys and supra-renal capsules, the cardiac portion of the stomach, the lower three-fourths of the duodenum, the pancreas, the ascending and descending colons and rectum, the uterus and bladder. That even in physiological conditions there are great variations in the mobility of these organs in different people is well known to everybody, while the changes in the length of their ligamentous attachments in conditions of disease are often such as to produce persistent dislocations. Generally speaking, however, and having a special reference to visceral injuries, and not to visceral diseases, the lists as given above would be correct.

If we consider the mobility of these organs separately, we may say that the ligaments of the spleen are usually long enough to permit it to be brought over to the median line without great difficulty. The stomach as a whole is quite an intractable organ. It is held firmly in place by the attachments of its cardiac portion, which is always an inaccessible portion of the viscus. The pyloric portion, on the contrary, and the first parts of the duodenum can be moved freely over a pretty large area. The liver, notwithstanding some notable exceptions, is quite solidly fixed in its place under the ribs by short, unyielding ligaments; and the gall-bladder, though more accessible than the bulk of the liver, is scarcely more mobile. The lower portions of the duodenum are not only solidly fixed in their position by the layers of peritoneum which bind them down, but are also among the most hidden and inaccessible of all the abdominal entrails. This gut has no mesentery, and for the most part lies behind the peritoneum. The liver and colons, meso-colons, and mesenteric vessels obstruct the operator who is obliged

for any reason to get at its anterior surface. The pancreas is immovable. The transverse colon is classed among the movable viscera; its range of motion, however, is confined to one direction; its centre may often be depressed nearly to the pubis and elevated to the ensiform process, but it cannot be moved very far in a lateral direction on account of the immobile condition of the ascending and descending colons, with which it is continuous. When these colons are bound closely to the abdominal wall, the transverse colon has almost no capacity for lateral displacement. When the ascending and descending portions have long meso-colons, the capacity for lateral displacement may be considerable.

The kidneys are of course immovable in their normal condition. The ascending and descending colons lie in some persons behind the peritoneum and have no mobility whatever, while in others they are partially invested by that membrane, and in others still they have short meso-colons. Even in these last-mentioned cases they can be drawn with great difficulty to the median line. The sigmoid flexure and cæcum are usually movable, with a somewhat limited range of motion, while the rectum and uterus, except in pregnancy or diseased conditions, are usually fixed in place. The urinary bladder may be distended until its upper portion reaches nearly to the navel, but its lower part is quite out of reach from an abdominal wound.

The most movable of all the viscera are the jejunum and ileum, which can be drawn at pleasure to almost any part of the abdominal cavity.

That which makes this one quality of mobility or immobility of such importance to the surgeon is, of course, the necessity under which he labors of making his incisions in the abdominal wall, in case of operations on any viscus, in such a way as to make that viscus accessible. It may be regarded as one of the misfortunes of the surgery of intestinal wounds that, thus far, the rules which have been established for the guidance of the surgeon in these cases have been founded on relations which concern only the movable viscera, while those of the immovable have been overlooked or ignored. Of the practical bearing of these anatomical relations I shall presently speak, after a short consideration of the nature of the wounds with which we have to deal.

Stabs and punctures are wounds made by daggers or other long, pointed, thin instruments, and are characterized by small orifices and long, narrow canals. They may be limited to the abdominal walls, or penetrate into the abdominal cavity and injure the abdominal viscera; they vary in depth according to the length of the instrument and the force with which it was impelled. A short weapon may, however, make a very deep wound, if the blow is struck with great force; the abdominal walls, yielding to the impulse, are indented by the weapon, and the resulting wound may be altogether disproportionate in depth to the length of the blade which inflicted it. Stab wounds are usually straight, although the blade before its withdrawal may sweep around the circumference of a circle whose centre is represented by the external wound; the narrow orifice may then lead into a wide and destructive wound. While one orifice means that the blade has entered but once, two orifices may either indicate two stabs or that the one thrust has transfixed the abdomen. If the circumstances are such that the surgeon can know that the two orifices are due to the one thrust, they will then be an invaluable guide to the direction of the wound The wounds inflicted on the viscera by stabs may be either incised or punctured. Only in rare cases, when a dull weapon has been thrust into the abdomen with great force, could such a wound be either contused or lacerated.

Gunshot wounds differ from stabs and punctures in the character of the injury done to the parts, and in the greater uncertainty which pertains to the course of the bullet. The size of the missile makes a vast difference in the gravity of the wound, and for this reason the experience gained in war from the destructive effects of rifle-bullets on the intestines may not be accepted as an absolute guide in the prognosis when we have to deal with the smaller missiles fired from revolvers and pistols. One wound means of course that the ball is still lodged in the body. The rare exception to this rule is the entrance of a spent ball into the body together with a portion of the clothing, and its subsequent withdrawal with the clothing. It might also mean that the surface of the body had been just touched by a glancing ball. Two or more orifices may be made either by one ball passing in and out or by two or more balls, or by one ball of which broken portions have escaped. When it is certain that only one shot has been fired, two orifices usually indicate the apertures of entrance and that of exit. They do not necessarily indicate, however, that the ball has passed in a straight line from one to the other aperture, for the deflection which it may suffer from the numerous obstacles which it meets may make its course more or less tortuous. These wounds have indeed become notorious for their irregularities, and there are many authentic histories of gunshots which have traversed the body in ways so erratic and peculiar as to defy explanation.

The study of these cases has produced a faith in their lawless character which is hardly justified by the actual facts. It has, indeed, so excited the professional imagination as to warp the professional judgment. Putting all fable aside, and studying the cases as they have really occurred, we will find that the course of a gunshot is determined by laws as rigid as any to be found in physical science. The deviations which it can make in its passage through the tissues are neither as many nor as great as is popularly supposed, and many so-called deflections are not deflections at all, but merely a secondary tortuosity of the wound caused by changes in posture. It may be stated as a general rule, which nobody will probably dispute, that the resistance which can deflect a gunshot from its course must be at least commensurate with the force with which the missile strikes the deflecting surface. It will always be deflected at an acute angle, and never at an obtuse or right angle. As regards the size of the angle, the general law will of course prevail, that the angle of incidence and angle of reflection will be equal; but this law will be modified in its action by many circumstances, and especially by the peculiarities of the substances upon which the missile strikes. A hard substance like bone may deflect a ball either at a large or at a small angle, or it may partially break and then deflect it, causing complex conditions. A soft and yielding tissue, however, cannot offer sufficient resistance to a gunshot, even though nearly spent, to deflect it, except when it strikes the surface at a very small angle. When the angle is at all large, the momentum of the ball overcomes the resistance and the tissues are penetrated. For this reason, balls which run around the body in the abdominal wall always strike it at a very acute angle, become deflected even when penetrating the skin, and thenceforth until their exit continue to be deflected by the overlying integument at angles so exceedingly minute that the whole course of the ball comes to represent a circle of large radius. Even then the resistance is finally overcome and the missile escapes. Whether such tissues as form the human intestine, or the softer tissues of the human body, can ever appreciably change the course of a bullet is, with me, a matter of great doubt, for the resistance which they can offer is so very small that they must either slip aside or suffer penetration. I am aware that I have the authorities against me in this matter, but the *à priori* considerations against this hypothesis are so strong, and the facts upon which it is founded are so easily explained by other and more reasonable hypotheses, that I feel compelled to regard it as, at least, an unproved theory. It must be conceded that the mere fact that a ball which has pursued a somewhat tortuous course in the body has bruised an intestinal

coil without breaking it does not prove that that intestine deflected the ball. The apparent deflections of the ball may be explained far more easily by the assumption of a subsequent change in the relative positions of the tissues. I think few men, even though medical men, realize how mobile is the abdominal wall, and how various are the shapes which it may assume. Accustomed to its rounded form, and to the even, rhythmic motion of breathing, we are apt to forget that every muscle is capable of a separate and individual action, which may altogether alter the shape of the whole. If we observe naked men in violent exercise, such as wrestling, it becomes apparent that the shape of the abdomen in action is ever changing. Now it is flat, and again it is round, or one side is flat and the other is round, or one portion is raised and another depressed. The history of phantom tumors, indeed, with their deceptive tumefactions, is sufficient to show of what the abdomen is capable. Now, men are shot often when engaged in violent struggles, and there can be no doubt at all that many a gunshot which has passed through the tissues in an absolutely straight line has been described as deflected on account of subsequent changes in the shape of the body. The only possible way to prove conclusively the power of the human intestines, or other similar tissue, to change the course of a ball would be to establish the facts by experiments instituted outside of the body, where the influence of all modifying forces can be carefully estimated. It is highly important, in any event, to remember that a soft tissue cannot possibly deflect a ball at any but a very acute angle. The human skin is a very tough tissue; but the histories of hundreds of cases in which a ball, striking it at an angle so small that the course of the ball must have been all but parallel to the surface, has nevertheless penetrated it instead of glancing off, will sufficiently show how impossible it would be for that or any softer tissue to escape penetration if the angle of incidence were very appreciable. If this theory is correct, the deflections of living balls from the straight line, measured, as they must be, by very acute angles, can never be very great in the short distance which they have to travel in the body, and in all probability those observations which would seem to prove otherwise should be explained on the hypothesis, not of a glancing ball, but of a subsequent shifting of tissues. Only when the missile strikes a bone can it glance off at an angle of good size. Many of the puzzles which surgeons have encountered are to be explained by the displacements of the dead ball—*i.e.*, of the ball whose momentum has been exhausted. It may then fall to the bottom of the cavity, follow the course of a canal, fall by gravity through the meshes of areolar tissue, or be carried along by muscular contraction. These changes of position do not affect, of course, the nature of the inflicted injury.

A ball entering the abdomen from behind may, immediately after entering the body, strike a bone and glance off at a considerable angle. The aperture of entrance and exit, therefore, of missiles from that direction throw little light on the course of the ball. It is otherwise with those which enter on the front or lateral surfaces of the abdomen. Missiles from the front or the side may deviate, it is true, from their course, and these deviations make it impossible to tell from an examination of the external wounds what organs may have been injured underneath. In this statement I am perfectly agreed with Dr. Parke and other authorities. Unfortunately, however, it has been assumed that because the situation of the aperture and the initial direction of the wounds cannot determine the actual course of the ball through the tissues, that therefore the study of these points is of little value to the surgeon as a guide in his operations. I cannot but regard this as a great practical error.

It is true that the exact course of a bullet in the abdomen cannot be determined prior to the operation, but it is not true that its approximate course may not be laid out with sufficent accuracy to guide the surgeon in his external incisions.

The tissues which can deflect a ball entering the abdomen from the front or side are, first, those of the abdominal wall and, second, those of the abdominal cavity. When once the ball has traversed the cavity and struck the opposite wall, its power to injure the abdominal viscera usually ceases. There are, of course, exceptions to this rule, where a ball, passing obliquely through the abdomen, strikes upon a rib, and glances to enter again into a viscus, but these exceptional cases are rare. Now, the greatest deflection suffered by such a ball before it escapes from the abdominal cavity is that caused by the skin and muscular walls. Should the missile enter these walls at a very acute angle, it may run around the whole abdomen and not once enter the cavity. When once it has passed through the abdominal wall, its further course is through soft and unresisting tissues, from which it can be deflected, if at all, only at a very acute angle. The course of the ball, then, from the point where it enters the cavity to that where it makes its exit from it, must be nearly in a straight line. Now, a careful study of the histories of many gunshot wounds of the abdomen, in which the ball has entered from the front or at the side, has convinced me that the course of a bullet through the cavity and its wall lies almost always in the same plane, so that a plane projected to any three points in its course will have within its limits the whole path of the missile. I do not mean to be understood, in saying this, that the path and the plane would coincide with a mathematical exactness, but that their coincidence would be near enough for all practical purposes.

The especial purpose of these studies is to determine, if possible, how the surgeon can best make his incision through the abdominal wall so as to arrive easily and quickly at the seat of visceral injury. The best men in this department of surgery have already agreed where the incision should be made, and where it should not be made—Parke, Dennis, Bull, Morton, and Nancrede, all lay down the law to the effect that the incision must be made in the linea alba, and that the wound must not be enlarged or disturbed except for purposes of exploration. I have as yet sought in vain for any adequate explanation of this rule, although the unanimity with which it has been adopted is something marvellous, when we consider the independence which surgeons manifest in other departments of surgery.

Parke states positively that "primary abdominal section in the mid line gives the best command over the damage done, and furnishes the most feasible opening through which the proper surgical treatment of such damage can be instituted." "The wounds of entrance and exit of the bullet *should not be disturbed* in any manner, except to control bleeding or to remove any foreign bodies when present. They need only to be covered by the general antiseptic dressing applied to the abdomen." And Dennis says: "The incision should be made in the median line. Any deviation from this rule is objectionable in many respects. The side incision does not permit the free exploration of the cavity, involves also dividing planes of muscles, the hemorrhage from which is troublesome to control and the primary union difficult to secure. The median incision divides no vessels of any importance, passes through the linea alba, which can be securely sutured, and is not likely to give rise to ventral hernia." "The enlargement of the original wound for an examination of the peritoneal cavity will not enable the surgeon to exclude in all cases fecal extravasation, perforation, volvulus, or hemorrhage." And Dr. Nancrede solemnly warns the practitioner never to enlarge the original wound unless it is located in the linea alba.

I confess that I have been unable to recognize in these arguments that decisive logic which solves all doubts, and I find myself in that most depressing of all situations—in a minority of one. *Why* should the wounds of entrance and exit never be disturbed? *Why* should the

incision never take in the original wound, unless that chance to be in the median line? *Why* may not the surgeon explore the abdomen with sufficent thoroughness by a side incision, if he make it long enough? There is no point in the abdomen through which an incision cannot be made as long as the linea alba in a straight line, if the surgeon chooses. Muscular hemorrhage may be troublesome, but it is not usually difficult to stop, and incisions through muscular tissues heal by first intention, as those gentlemen can testify who have had experience in operations upon the stomach in which the incisions have been made parallel to the ribs through muscular planes. I have yet to learn that these operations have been followed by an undue number of ventral herniæ. But while the reasons adduced for forbidding all but the median incisions are not convincing, there are many very cogent reasons for departing from that rule in many cases. Take, for instance, the case of any one of the immovable viscera. It may not in case of injury be possible to reach such a viscus from the median line, except by enormous incision, and it may be possible to reach it by a short cut if made in its neighborhood. Are we prepared to accept the doctrine that a cut of twelve inches in the linea alba is less dangerous than one of four in the muscular wall? I had, myself, last winter, a case of gunshot of the ascending colon and cæcum, which will illustrate.

Maggie McM——, aged twenty-four, was shot in the abdomen at three o'clock on Tuesday morning, December 21, 1886. She was carried to St. Mary's Hospital at half-past eight o'clock, and I saw her at nine o'clock on the same morning. I found her vomiting bile and complaining of great pain. Her pulse was 120 per minute, her respiration 30, and her temperature 102° F. The bowels were moderately bloated and very tender, and two inches above and two inches inside of the right anterior superior spine of the ileum there was a gunshot wound with black edges. There was no tympanitic resonance over the liver, no extravasation of fecal matter, no emphysema, and no general meteorism. The pain was located in the hypogastric, right iliac, and right lumbar regions. The wound was supposed to have been made by a ball from a revolver of 32-calibre, although that point was never fairly settled. At twelve o'clock, noon, I cut through the abdominal wall at the site of the wound, making an incision four inches long in the direction of the fibres of the external oblique muscle, the wound being in the centre of the incision. It was easy to trace the wound into the abdominal cavity by the discoloration of tissues, and it soon became evident that the ball had passed from before backward, and from above downward, into the peritoneal sac. My finger, on entering the cavity, immediately detected a hole on the anterior surface of the ascending colon, which I thereupon drew out onto the abdomen. This wound, from which fecal matter was constantly pouring, was an oval, with its long axis transverse to that of the intestine. It was about half an inch long and a quarter of an inch wide. I sewed it up with a continuous suture of catgut, in a double row, after Czerny's modification of Lembert's method. Searching then for the wound of exit, I found it also vomiting fæces directly behind, at the junction of the meso-colon with the intestine. The meso-colon and meso-cæcum in this case were as long as the peritoneum, completely surrounding the gut. The ileum was united to the intestine on its inner and posterior surface, midway between the two wounds. The second wound had its long axis also transverse to that of the bowel, and was sewed together in the same way as the first. This done, I was able to trace the track of the bullet down into the femoral canal, in front of the external iliac and femoral arteries, by a ragged opening in the muscle, but its course afterward was a matter of great uncertainty. I carefully examined the small intestines without withdrawing them from the cavity, but found no other wound. The abdominal cavity was washed out and closed with wire sutures, and a drainage-tube inserted. The patient began immediately to improve, and her temperature fell a degree on the same day; she vomited less frequently, and the ejecta contained only mucus and swallowed fluid. Her pulse fell to 100, but her temperature rose again, on the second and third days, to 102°. After the third day the improvement was more marked, and after the sixth she ceased altogether to vomit and her temperature fell to 99° and 100°. The drainage-tube was then withdrawn, without having discharged one drop of pus. Subsequently, however, a small superficial abscess formed in the track of the wound, and on the tenth day discharged a teaspoonful of pus. Her convalescence was thenceforth uninterrupted, and she left the hospital, February 2d, suffering only from a lameness consequent upon the passage of the ball into the thigh. There were present at the operation Dr. Perley, U.S.A., Dr. H. O. Walker, Dr. N. W. Webber, Dr. Shurley, Dr. Boise, Dr. Robbins, and others.

Now, in this case I called the attention of the gentlemen present to the difficulty which I should have experienced in reaching the wounds in the gut, and especially that one on its posterior surface, had I made the usual incision in the linea alba. It would have been simply impossible for me to have got at it without cutting the wound from the ensiform cartilage to the pubes and eviscerating her; whereas, with a short incision, I was enabled with ease to perform the necessary manipulations on the bowel and to carefully examine the small intestine. I have since, several times, on occasions of post-mortem examinations, endeavored to bring the ascending colon out through an incision in the linea alba, as it would have to be drawn out for purposes of operation, and have every time found it to require a long incision, and even then to be a matter of great difficulty Here, then, was one case, at least, in which a great error would have been committed by adhering to the arbitrary rule of median incision. But that which was found true of the ascending colon would be found to apply equally to the descending colon, stomach, and liver. There is no way in which an immovable viscus can be made so accessible as by an incision parallel to its long diameter.

Even in operations upon the pylorus, which is quite free and movable, many surgeons have preferred the transverse or oblique incisions to that in the linea alba, because, as Wolfl says, "first, the diseased portion is more readily got at; second, the remaining portions of the stomach can be more easily examined; and third, the existing adhesions to the peritoneum can be more easily excised. And besides these, for the further reason that the intestines are less readily prolapsed than in the median incision" (Dr. E. Kish, *Langenbeck's Archives*, vol. xxvii., part 4).

How much more, then, in excisions of the movable pylorus, is the transverse or oblique incision indicated in those gunshot wounds of the stomach in which both walls are perforated, and in which the posterior wound may lie very near the cardiac orifice? In such cases the incision perpendicular to the long axis of the organ puts the surgeon to a great disadvantage, while a cut transverse or oblique, or even slightly circular, under the ribs, enables him to expose the whole organ and draw it out into view. The perpendicular cut in the linea alba, in case of gunshot wounds of the liver, enables the surgeon to feel the liver's edge and to pass his fingers for a short distance over its surfaces. He can neither examine the organ as a whole nor inspect its lower surface, while a transverse cut just below its edge will bring the whole viscus into the field of operation and enable him to operate even on its under surface. Let us apply these principles to gunshot wounds. The first points to determine are whether the wound is a penetrating wound, and if so, what viscera have been hurt.

Without discussing the question of diagnosis, on which I have nothing new to offer, I will say that it is generally conceded that there is no other way to determine the

question of penetration except by following the track of the ball until it either enters the abdominal cavity or leaves the abdominal wall; or if the track is too long, then by boldly opening the abdomen elsewhere for purposes of exploration. The question of whether to follow the one or the other of these procedures must be left to the judgment of the surgeon. It is evident that one could not follow the track of the ball if it led across the whole width of the abdomen. It is equally clear that one ought not, without due cause, to open the peritoneal cavity. Probably the best rule to follow is for the surgeon, in cases of doubt, always to begin his work by exploring for a short distance the track of the ball. If then it leads him quickly into the abdominal cavity, he learns that fact, and can proceed accordingly. In any event, he learns the initial direction of the missile and can form some judgment as regards its further course. I think that all must admit the practical worth of the knowledge thus acquired. The conviction has been so strong that the ways pursued by gunshots were utterly erratic and unaccountable that surgeons have come to discard all indications as of no service in actual diagnosis. This extreme view is certainly not justified by any larger experience. That no man can say before exploration exactly what organs are wounded is certain, but any surgeon with good judgment, after a careful examination of the course of the ball through the abdominal wall, can say about where the missile is gone and what viscera it may have hit. The course of a ball from the time it enters the abdomen until it strikes the opposite wall *must* be nearly in a straight line, for the reason which I have mentioned; and if it were not for the shifting of tissues and changes in shape which occur subsequent to the shooting, comparatively little difficulty would be experienced in tracking the bullet. As it is, the initial course of the ball reveals much that is of inestimable advantage to the operator. If a bullet enters two inches to the right of the navel, and passes from left to right and downward and backward, the surgeon knows positively that it has not hit the spleen, nor the stomach, nor the liver, if these organs are of normal size and in normal position. He knows absolutely, too, that such a ball could not possibly hit any organ which did not at the time of the shooting occupy a position downward, backward, and to the right of the aperture of entrance. In this hypothetical case it might hit the transverse colon or the small intestine, or the ascending colon or cæcum, or a mesentery or meso-colon, or some blood-vessel. Now, an incision through the abdominal wall, beginning at the wound and carried a sufficient distance downward and outward in the line of its track, would suffice to enable the surgeon to examine every organ injured, and to repair every injury. Every injured viscus could be brought into the wound, and no viscus which could not be brought into the line of the incision could possibly have been injured by the missile.

The rule which seems to have met the general approbation, that every inch of the small intestine must always be examined in a gunshot wound of the abdominal cavity, must surely be reconsidered. How, for instance, in such a wound as I have described, could the duodenum possibly be injured at its pyloric end? How, in a gunshot wound above the navel, in which the course of the wound passed from before and below, backward and upward, could the missile possibly come in contact with the lower part of the ileum? How, in any wound, could any viscus have suffered injury, which could not by gentle traction be brought into view through an incision which, beginning at the aperture of entrance, uncovered the whole course of the ball? Let us take another hypothetical case, that of a gunshot wound of the right hypochondriac region, in which the ball, entering three inches above and two inches to the right of the umbilicus, passes obliquely upward and backward. In this case, while it may not be beyond the bounds of possibility that a coil of the jejunum or ileum might be wounded, yet such an event would be extremely improbable; would it then be good practice for the surgeon to haul out these viscera into the cold in order to satisfy himself that a wound *did* not, which in the nature of things *could* not, exist?

Two cases from the current literature will illustrate this better than any hypothetical cases. In one case a ball entered a little to the left and above the navel. With the accustomed indifference of surgeons nowadays to the course of the wound, the wound does not seem to have been examined in order to find out its direction. From the fact that the ball perforated both walls of the stomach and both walls of the duodenum, it is fair to infer that it passed from below and before, upward and backward, and from left to right. Notwithstanding that it was utterly impossible for such a ball to injure any of the lower parts of the intestines, the whole intestinal tract was examined down almost to the ileo-cæcal valve.

In the second case the ball entered over the ninth (?) rib, three and three-fourths inches to the right of the median line and four and a half inches above the navel (there must surely have been some mistake in these measurements), and was found one and one-half inch above the navel and eight inches to the left of the median line. It grazed the liver, perforated the stomach, wounded the small intestine in the left flank (the jejunum), and lacerated the left kidney. The surgeon subjected the entire bowel, from the stomach to the sigmoid flexure, to a close examination—but why? The lower portions of the duodenum, the greater part of the ileum, the ascending colon and cæcum, and the lower part of the descending colon and sigmoid flexure could not possibly have lain in the course of the ball. Both of these cases died, and it may not be impertinent to ask if the unnecessarily prolonged manipulation and exposure of the intestines had anything to do in causing their deaths? I do not wish, in criticising these cases, to be understood as reflecting in any way upon the practice of the two surgeons, both of whom I greatly esteem. They were perfectly justified in their manner of operation by the prevailing professional public opinion. I wish, however, to express emphatically my opinion as to the utter senselessness of a rule which requires the surgeon to examine and expose viscera and portions of viscera which could not possibly, in the nature of things, have suffered injury. The only explanation, indeed, which I can make for its adoption is the queer belief, prevalent in the profession, that a gunshot has the power to run around the abdominal cavity, regardless of all natural law.

It is curious how the adoption of a theory will influence men's ideas and practice. I believe it is a well-established rule in abdominal surgery that the longer the incision the greater the danger. Lawson Tait's great success has been ascribed by some to his remarkable skill in operating through small incisions, and yet, in the matter of operating for intestinal wounds, surgeons have seemed to persuade themselves that it made no manner of difference whether the abdomen was split in the median line from ensiform cartilage to pubes. Dr. Morton says, indeed, that there is no harm in a long wound if properly treated. I must protest earnestly against this kind of teaching. There *is* harm in a long wound even though properly treated, and when the surgeon makes one longer than is necessary he thereby unnecessarily endangers the patient's life. It is not only that the danger of infection is greater in a long wound, but also the danger of shock, the danger of chill, the danger of prolonged etherization, and the danger of exhaustion. I have had many a patient under my hands, whose life or death seemed to me to depend upon the time in which the operation could be got through with. I do not mean to say that the surgeon should ever allow himself to make an incision too short to accomplish his purpose. On the contrary; but I strongly suspect that hitherto, while the incisions in the linea alba have been in some cases made too long for safety, those which have been made in the track of the wound have been too short to be effectual.

I have tried, by studying the cases already published, to come to some definite conclusion as regards the relations which are borne by the direction of the wounds in the abdominal walls to the wounds of the viscera underneath, but have failed to come to satisfactory conclusions on account of the defective character of the reports. In most of the reports the position of the wound is given, but its direction through the abdominal wall is altogether ignored—a circumstance which indicates forcibly the neglect into which this most valuable indication has fallen. Before we can, however, come to a conclusion as to what wounds demand median incisions and what wounds demand incisions elsewhere, what wounds demand examination of the whole intestinal tract and in what wounds that tedious and dangerous examination can be dispensed with, we must have at our disposal large numbers of accurate records in which the position of the external wound, its course through the abdominal wall, its subsequent course through the cavity of the abdomen, and its termination, together with all other details, are reported so exactly as to permit of critical study. In the meantime, every surgeon who operates must be left unhampered by arbitrary rules, to make incisions and to follow operative methods according as his judgment dictates in any individual case.

When the abdomen is opened and the visceral wounds discovered, they must be repaired. In considering these repairs, we have to distinguish between those of the hollow and those of the solid viscera. Injuries of the intestinal wall must be invariably sutured with the Lembert suture. Many efforts have been made to improve this suture without success, unless Czerny's modification may be so considered. I have myself made very many experiments in this direction, which I will note here for the purpose of pointing out a false way, into which someone else might blunder. I conceived the idea, after reading accounts of cases in which the Lembert suture had failed to hold the wounds together, that the intestine might grow together more rapidly and with a stronger union if the opposing surfaces were made raw by denuding them of their serous coverings. On the thick intestinal wall of the dog this is quite practicable. The serous membrane can be easily dissected with the fingernail from the muscular wall, and there will be left a thickness sufficient to hold a fine suture without having the needle pass through the mucous membrane. I operated on a great number of dogs after this fashion. Opening the abdominal wall, a gut was seized and brought to the surface. A circular cut was then made through the serous coat of the gut. This was dissected up on each side of the cut, and turned back like the cuff of a coat. It was wonderful to note the contractile power of the serous coat when free from its attachments. It would then contract to half its previous dimensions. When the serous coat had been turned back, the intestine was cut through and the remaining walls cut partly away. The resected ends were brought together by sutures passed through the muscular layer alone, and then a second row through the shrunken and sometimes curled-up serous coat made the union secure. In some cases I, at the same time and on the same dog, made two resections, one by this method and the other by Lembert's method, in order to compare the two kinds of stitches. The most of my dogs survived the operation, and, as far as that goes, my operation could be considered a success, but a careful comparison between my own method and Lembert's proved conclusively the superiority of the latter. The serous surfaces not only healed together with less inflammation and suppuration than the raw, but the union could, after the same lapse of time, endure a greater strain.

Besides that, I satisfied myself on the cadaver that my method was quite impracticable on the thin-walled human intestine, and I abandoned it. I do not believe that any other method will ever supplant that of Lembert, and the only question is, Which of the various modifications is most useful? I have adopted a continuous suture which I believe will make the patient nearly absolutely secure against any failure in union or extravasation of fæces. In the case I have just reported I began the suture at a little distance from the end of the wound, by carrying the thread through the serous and muscular coats and then knotting it, leaving the end long. A continuous suture was then carried along the whole course of the wound and a third of an inch beyond it. The suture was then carried back at a higher level, after Czerny's method, until the point of beginning was reached, and then the thread was drawn tight and the two ends tied firmly together. It does not matter what kind of a continuous suture is used, if the insertions of the thread are near enough together. The continuous suture is, in my judgment, better than the interrupted, both on account of its greater security and because it can be applied much more quickly.

There is another question in connection with these intestinal wounds, and that is, What wounds, if any, require resection of the bowel? Madeling has shown conclusively that any considerable destruction of the mesentery will insure gangrene of that portion of the bowel whose afferent blood-vessels are thus destroyed. The case of Dr. Keen's, reported at the last meeting of the American Surgical Association, corroborates Madeling's observations. If I understand his description, he found, on post-mortem examination, opposite the injury to the mesentery, a gangrenous spot as large as a five-cent piece.

Pending further experience on this point, we may say, then, that great injury of the adjacent mesentery may demand excision of that portion of the bowel with which it is in contact. I do not believe that any other form of injury can ever demand excision, or be treated by any other method as safely and successfully as by suturing the wounds. Even such multiple wounds as Parke describes, and for which he counsels excision, will heal perfectly well by simple suture. Some experiments made upon dogs by myself and my assistant, Dr. F. W. Robbins, will illustrate this point. My object in operating was to find out what could be done by suturing multiple wounds near to one another in a gut instead of resecting the gut. I therefore, in each case, drew out the small intestine and cut holes, with a pair of scissors, from one to two centimetres in diameter. In one case they were made six in number, on one and the same side of the gut. This animal recovered, and was afterward operated upon by having two holes cut, each a centimetre in diameter, on opposite sides of the gut and directly opposed. He recovered a second time. In a second animal four holes were cut near one another, but irregularly placed. This animal got well. A third, operated on on a dark day, died, and the sutures were found to have been imperfect. There were in all six operations, followed by one death. In closing the intestine, it was drawn together in such a way that the edge of the wound was transverse to the long diameter of the gut. In this way the lumen of the gut was enlarged instead of narrowed at the seat of injury, whereas if it had been made parallel to the longitudinal axis the lumen of the intestine would have been lessened. If a wound were so located, however, that its edges could be brought together only in a longitudinal line, the surgeon could, nevertheless, close it in this way without fear of obstruction. Mikulicz closed, in one case, the defect in the bowel by a longitudinal suture, which made a considerable narrowing of the gut at that point. The patient nevertheless recovered, and suffered no subsequent symptoms of obstruction. Few people seem to realize the elasticity of the intestinal wall. It will stretch, especially in a longitudinal direction, like india-rubber, and this elasticity enables it to recover its tone and shape after injury and loss of substance. For this reason I must dissent from the practice, which has been recommended, of excising the

intestine for multiple wounds. Where the interval between the two wounds is too small to permit the insertion of stitches, the bridge should be cut away and the two wounds turned into one. But however many the wounds, they should all be sutured without resection, and the operation of resection reserved for those cases in which the vascular connections of the gut have been widely destroyed.

Wounds of the solid viscera have not yet been subjected to sufficient experimental study to enable the surgeon to form an opinion as to the best method of treatment. I have myself operated on three dogs by incising the edge of the liver and closing the gap by deep sutures. The bleeding was not very considerable. I passed sutures of fine silk or catgut deep into the liver-substance and thus closed the wounds. On one of the animals an operation was simultaneously performed on the stomach. This one died after twenty-four hours. The edges of the cut liver had become agglutinated. The other two recovered.

The slight consequences, comparatively speaking, which have followed incisions into the liver for abscess should give rise to good hope in case of a wound of this organ not involving the large veins. The treatment of such a wound should be either by suturing it finely and deeply with catgut, or by stuffing the wound in the organ with iodoform gauze and keeping the wound in the abdominal wall open for drainage. This last course was pursued successfully by Dr. H. Burckhardt, of Stuttgart. This surgeon was called, on March 29, 1886, to see a man who was collapsed from a stab in the mammillary line just below the ribs. As the patient was evidently dying of internal hemorrhage, Burckhardt made a cut in the abdominal wall of twelve to fourteen centimetres in length, beginning at the wound; found the abdomen full of blood, the source of which proved to be a wound three centimetres long in the left lobe of the liver. He stuffed iodoform gauze into the wound and stopped the hemorrhage by compression. The patient recovered.

Whether a gunshot wound of the kidney or spleen should demand excision of the organ is a question which further experience must answer. Wounds of the pancreas should be treated according to the principles laid down by Dr. Senn, in his admirable monograph on that subject.

I shall in this paper discuss only one more question, that, namely, as to the class of penetrating wounds on which the surgeon should refuse to operate. The rule to perform laparotomy for penetrating wounds will surely be found to have many exceptions.

One of these exceptions may, or may not, be the wound of an empty stomach. A case from my own practice will illustrate this point.

Thomas J. H——, a medical student, was the happy possessor of a revolver, which he was accustomed, at night, to keep under his pillow. He arose on the morning of July 17, 1879, and, for some reason, jerked the sheet from off the bed. With the sheet came the revolver, which fell upon the floor and discharged one of its barrels. The ball struck him a little above and to the left of the navel, and its course was from below upward and, presumably, to the left. I was called, and arrived within half an hour. He had then vomited blood, and once again vomited blood. He had eaten a light supper at six o'clock, and had taken nothing into his stomach since. The wound was not probed, but from the position in which he stood at the time of the accident, and which was described on the spot, I judged that its course through the tissues was from right to left, from below upward, and from before backward. He was put to bed, placed under opiates, allowed for several days neither to eat nor to drink, but was fed wholly by enemata, and he recovered, not, however, without suffering from a severe traumatic peritonitis, during which he experienced great pain and his bowels became enormously bloated. In this case there can be little question that the stomach was wounded, and that the time of injury, in the early morning, when the viscus was empty, had everything to do with the subsequent favorable course of the wound.

Dr. Keen's case illustrates, probably, for the condition of the stomach as respects its contents is not noted, the same point. The girl shot herself at 6.30 A.M., and we may presume that she was then fasting. Dr. Keen especially remarks that there was no extravasation of the contents of the stomach and the wounds could hardly be discovered. The stomach is indeed much more tolerant of injury than is usually supposed. A remarkable case was that of Professor Von Mosetig's, published in the Vienna *Medical Wochenschrift* of December 18, 1886. On November 17, 1886, a man, thirty-one years of age, shot himself in the left side, the ball entering the fourth intercostal space a little outside of the nipple. There was no wound of exit, but in the back, between the tenth and twelfth ribs, there was a hard spot. The patient showed no gastric distress, no tenderness of the bowels, and no vomiting. He had hæmato-thorax on the left side, and suffered greatly from dyspnœa. During four days he had no fever, and ate heartily and regardlessly. On November 21st he was seized with erysipelas of the face, from which he had on November 30th recovered. He remained free from fever for the next two days, when on the third day a rise of temperature preceded the discharge through the wound of a large quantity of offensive pus and blood. The hard spot on the back was then opened, and the bullet found and extracted. The finger extended here into a cavity containing a large amount of black, putrid matter. No communication could be established between the two orifices, but when the patient vomited, on awakening from the anæsthesia, he discharged from the stomach some of the permanganate of potash solution which had been injected into the wound. After that, food was from time to time discharged through the posterior wound. The patient remained free from fever, but on December 8th died suddenly, from causes not stated in the narrative. The autopsy revealed a communication of the anterior opening, through the cavum pleuræ, diaphragm, and left lobe of the liver, with the stomach, both of whose walls had been perforated. Here, then, had been a frightful wound of the pleural cavity, stomach, and liver, in which the only symptoms of trouble, during several days, had been those caused by hemorrhage into the pleural cavity. Von Mosetig assumed that the stomach at the time of injury had been empty, and had quickly formed adhesions to the surrounding organs.

I have myself, in connection with Dr. Robbins, made a few experiments on dogs, in order to determine the effect of wounds on the empty stomach. The dogs were all kept fasting for twenty-four hours, and then operated on by drawing the stomach out, stabbing it in one or more places, and then returning it, unsutured, into its place. The wound in the abdominal wall was then securely sutured and the animal kept fasting for forty-eight hours, with sparing allowance of water.

Case I.—February 25, 1887. Medium-sized dog, fasting for twenty-four hours. The stomach was drawn out and both anterior and posterior walls perforated simultaneously by passing a scalpel through them. This double puncture was made twice, with an interval of half an inch. The stomach was then replaced and the abdominal wound sutured. The animal was then kept fasting, but was allowed a little water. After forty-eight hours he was fed on milk. He recovered without a bad symptom. The wounds through the stomach-walls were about half an inch long.

Case II.—Black dog, medium size, fasting, was operated on as above, making, however, but one double wound. Died twenty-four hours after operation. There were found, on post mortem, evidences of great peritoneal congestion. In the abdominal cavity there was about

an ounce of bloody fluid. The stomach was half filled with thin, yellowish fluid. The anterior wound had healed, except at one corner, where there was an opening as large as a pin's head. The opening in the posterior wall, where the knife had been passed, had so thoroughly healed that even its location could not be discovered.

Case III.—February 26, 1887. Dog of medium size, fasting, was operated on as before, by grasping the stomach and transfixing both walls. This dog made a quick and complete recovery. The hole in the stomach was one centimetre long.

Case IV.—February 26, 1887. Dog operated on as above, but the incision in both anterior and posterior walls measured half an inch. This dog recovered.

Case V.—Scotch terrier. I operated on this dog as above, and, besides, cut a gash an inch long in the edge of the liver. He died in twenty-six hours. About three ounces of red fluid was found in the peritoneal cavity. The wound in the liver had become agglutinated outside, but not in the depths of the wound. The wound in the anterior wall of the stomach could not be detected from its peritoneal aspect, but the mucous membrane was marked by a linear slit. On the posterior wall a discolored spot on the peritoneum showed the site of the wound, which, however, was closed, but the mucous surface had not healed.

It was astonishing to note, in the cases of death, how quickly nature had repaired most formidable injuries, for in both cases one of the wounds had healed so thoroughly, by first intention, that its site could be with great difficulty detected.

It cannot be denied, in the face of such evidence, that wounds of the empty stomach, though perforating both anterior and posterior walls, may have a good prognosis, and yet I should hardly venture to say that the penetrating wounds which are located in the region of the stomach and involve that organ should be exempted from the general rule of exploratory laparotomy.

The difficulty of excluding injury of other viscera, and especially of the liver and colon, would seem to make abdominal sections imperative even in those cases.

When, however, from any other cause, the operative procedure should seem to be of doubtful propriety, the facts which I have just related might make the expectant treatment more justifiable.

A condition which would seem to me to more positively forbid abdominal section is that of great obesity. The case reported by Dr. Briddon illustrates one objection to operating on such cases, namely, the difficulty in performing the operation through several inches of fat. The surgeon in such a case is cramped for room in which to work, and is further hindered by the difficulty in distinguishing the various tissues within the abdominal cavity. This is so great in cases of vast intra-abdominal accumulations of fat that physicians are puzzled, even in post-mortems, to distinguish the relations of organs. How much more so must be the case in operations during life, in which the external incision must be limited?

There is, however, an even more weighty objection to these operations, and that is the difficulty of possessing an absolute asepsis where the necessity of the case forces the surgeon to break an incalculable member of fat-cells and to leave in the abdominal cavity an immense quantity of disorganized free fat. With all that, he has to do with the patient who belongs to a class notorious for their slight powers of resistance to traumatism. For these reasons the outlook of operations, especially on persons in whom there are likely to be multiple wounds of the small intestines, is gloomy enough. I do not mean to say that such cases are to be always considered as inoperable, but that the accumulation of fat must be reckoned among the circumstances unfavorable to operative procedure.

The persistence of great shock, if only it could be distinguished from the collapse caused by internal hemorrhage, should contra-indicate the operation for the time; but as the differential diagnosis between the two conditions is often impossible, the surgeon will frequently find himself in a dilemma between the indications caused by a possible hemorrhage or those caused by a possible condition of shock.

The occurrence of peritonitis, although of disastrous import, should not in itself, in my opinion, contra-indicate laparotomy.

In conclusion I wish to urge upon the profession the consideration of the following propositions, not as dogmas for adoption, but as theories and facts for discussion:

1. There are many viscera in the abdomen which are practicably immovable—so immovable as to forbid operations upon them through the median line. When a gunshot wound is so located and so directed as to make the injury of an immovable viscus probable, the external incision should be made with reference to that fact.

2. The course of a gunshot wound is determined, not by chance, but by the operation of immutable laws.

3. When a gunshot is deflected from its course, it is always at an acute angle, and when deflected by a very soft substance, of little resistant power, the angle of deflection must be exceedingly small. When, therefore, a gunshot passes into the abdominal cavity, the deflection of the ball, from the time it leaves the aperture of entrance until it strikes the opposite wall, cannot be sufficient to appreciably alter its course.

4. The initial direction of the ball through the abdominal wall indicates very nearly its subsequent direction through the abdominal cavity. The careful study of the wound of entrance is, therefore, of the greatest importance, and no surgeon should open the abdomen for the repair of visceral wounds without first exploring the wound of entrance sufficiently to make sure of its course through the parietes.

5. The ball, after passing through the abdominal cavity, may be deflected by the bones or soft tissues, but as it in the vast majority of cases pursues the remainder of its course outside of the abdominal cavity, these deflections should have no influence in determining the line of incision.

6. Gunshot wounds of tortuous course frequently owe their apparent deviations from the straight line to a change in the shape of the abdominal wall subsequent to the shooting.

7. In general, the course of the bullet through the abdominal wall, prolonged by a line drawn on the external abdominal surface, will indicate the course of the bullet through the cavity if its velocity is great. If at angles of five, or of not more than ten degrees, with this line two other lines are drawn on either side of it, beginning at the wound of entrance, we will have represented on the abdominal surface the greatest deflections of which a bullet is capable during its passage through the abdominal cavity. An incision, therefore, along the whole length of the first straight line could not fail to uncover every part of the course of the ball, provided that there had been no subsequent displacement of the injured tissues.

8. For this reason an incision beginning at the wound of entrance and prolonged to a sufficient distance in its course is often the very best which the surgeon can make. This is especially true of such wounds as, beginning at a distance from the linea alba, pass in a direction away from that line.

9. The immovable viscera can be best exposed by incisions made parallel to their long diameters.

10. When abdominal section is made for penetrating wounds, every organ and part of an organ which could possibly have lain in the path of the ball or weapon should be thoroughly explored by the surgeon, but to examine an exposed viscera, or portions of viscera, which

could not possibly have been injured would be an error in practice.

11. The prognosis of wounds of the empty stomach is not necessarily bad.

12. Large accumulations of fat in the abdominal wall and cavity may sometimes contra-indicate laparotomy for visceral wounds.

A CASE OF DISSECTING ANEURISM ABOUT THE HIP, DEPENDENT UPON RUPTURE OF THE INTERNAL PUDIC ARTERY.[1]

By V. P. GIBNEY, M.D.,

NEW YORK.

The case presented in this report is certainly interesting, both to the general and to the orthopedic surgeon, and it seems to me unique. At all events, I am quite sure that it is exceedingly rare to find a tumor of this nature in orthopedic practice.

I have made no extended search through the literature of ruptured vessels, but have consulted the "Index Catalogue" without finding any direct reference to this subject.

Without anticipating the points, I will simply present the facts in connection with the case.

On March 24, 1887, I saw, in consultation with Dr. Charles Carroll Lee (to whom I am indebted for the privilege of presenting this case), a lad fifteen years of age, the object of the consultation being a question as to diagnosis. I learned on this date that the boy, a member of a large family whose history was good, had himself always been regarded as wiry and active, yet had been the subject of some anxiety for a year or more. In the early summer of 1886, on account of some indisposition, Dr. Lee gave him a thorough examination, finding a double valvular lesion of the heart. This was confirmed by Dr. Loomis, who was consulted at that time. It was concluded then that the heart lesion was probably congenital.

The boy spent the summer at a watering-place, and early in the fall he fell from a bycicle. Apart from a few bruises, nothing in the way of injury was found; indeed, he was just as active during the rest of the season, and throughout the winter, as he had ever been. There was no lameness whatever. He spent a part of the winter in Havana.

On March 1st, without any provocation, he began to walk a little stiffly, favoring the right limb. He continued to walk lame, and on March 7th, the day before the time appointed for return to his home, a play-fellow gave him a pretty sharp blow with his fist over the right hip, the one he had been favoring for the past week. The report from both the boy and his mother is, that a sharp pain was experienced as an immediate result of this blow, and that the lameness increased. He suffered much the same night. He suffered so much pain that the family determined to reach home as quickly as possible, and came by rail from Florida. There was some swelling about the hip on the day of their departure. Before he reached New York the suffering had become so great that it was with difficulty he could be moved about. Dr. Lee saw him on his arrival in the city, and discovered a little fulness about the hip, but it was not sufficiently circumscribed to attract special attention. The extent of the heart-murmur, and the probability of exposure to cold, especially at night, in the South, naturally suggested rheumatism, and it was thought best to keep him in bed. This was about March 12th.

One week later the swelling had increased so that fluctuation was discovered, and the possibility of an abscess suggested itself. His temperature varied from 100° to 102° in the afternoon. His appetite was capricious, and he began losing flesh. On March 23d, Dr. Lee introduced a hypodermic needle into the tumor, but failed to discover anything by this procedure.

On the occasion of our examination, on March 24th, we found an immense fulness extended from the crest of the ilium on the right side to the middle third of the thigh. The fulness was quite uniform, there was deep fluctuation, but the surface heat was not marked. There was no joint tenderness, no crepitation or grating within the joint, and the arc of motion, although small, was limited only by the amount of swelling about the hip—that is, there was no sign of reflex spasm produced by attempts at motion; the limb below the tumor was not smaller than its fellow. We introduced an aspirating needle in three or four different places, with negative results. The appearance of the tumor, the absence of pulsation or bruit, pain on movement of the hip, and the temperature curve, induced us to regard this as a case of acute subfascial abscess, or what we might term an acute suppurative periarthritis. It was decided to employ a longer needle at the next visit, and if it was found necessary, lay the tumor open and treat antiseptically.

March 25th.—The tumor has increased perceptibly in size; the skin is quite tense. The boy has required morphia to secure rest, and his general condition has not changed for the better. With a long exploring needle an effort is made to discover the contents of the tumor. Several punctures are made on the outer side of the limb, without any result. Finally, the needle is inserted over the sacro-sciatic foramen, and after pushing the point in different directions, the barrel of the syringe finally fills with blood. The color is suggestive of arterial blood; yet, on removing the syringe from the needle, the blood flows with very slight force. The needle is removed, the bleeding soon ceases, and a compress is applied.

On March 30th I saw the patient again with Dr. Lee, and the report was that the boy had suffered considerably since the 25th, and within the past day or two had referred the pain to the inner side of the knee and down toward the foot. His temperature has been a little higher than previously, reaching 103° on one or two occasions. The tumor has increased in size on the outer side of the thigh. About the middle is a small circumscribed tumor lying upon the original tumor. At this point there is distinct fluctuation. On exploration we find the blood darker than previously, and two or three ounces are removed by the syringe. Each of us take a specimen for examination. We are fully convinced now that the tumor is dependent upon hemorrhage.

March 31st.—A microscopic examination reveals very little except blood. The blood-globules are somewhat crenated, but not specially degenerated. This is the report of our two separate examinations.

April 1st.—The question of operative interference has forced itself upon us; indeed, the former diagnosis of abscess has long since been given up.

Dr. E. L. Keyes is called in consultation this afternoon. The tension has increased since yesterday, the acumination is more pronounced, and there is some reddish discoloration over the surface. His temperature last night was 104°, and he is unquestionably losing flesh. Dr. Keyes makes his examination with a needle, finding darkish blood, the flocculency of which disappears after standing a while in the basin. In his opinion it was thought best to wait longer. He prefers not to make a diagnosis. He seems surprised at not finding pus. We all agree that there is nothing malignant about the tumor.

April 3d.—After consultation this afternoon, it is decided to make a small incision into the tumor, the parts being first cocainized. It is regarded as a hazardous procedure to use ether or chloroform, on account of the condition of the heart; but Dr. Lee attends personally to the anæsthetic, while Dr. Keyes makes the incision. The bistoury is thrust into the tumor on the outer side, and immediately thereafter a gush of blood follows. The opening soon fills with clots, and as these are removed

[1] Read before the Orthopedic Section of the Academy of Medicine, May 20, 1887.

the flow of blood continues. It becomes evident that a vessel is bleeding in the deepest portion of the tumor, and, under ether, a free crucial incision is made. The contents, consisting of blood-clots and blood, are quickly turned out, when the internal pudic artery is found bleeding. The work has to be performed so expeditiously that it is considered unsafe to spend much time in trying to pass a ligature about the artery. Two clamps are forthwith applied, and these are tied into position while the wound is packed with absorbent cotton. The whole operation does not last fifteen minutes; the patient rallies well. Morphia is administered to secure rest.

The operation was made at four o'clock. The pulse continued good all the evening; but between one and two o'clock the following morning the patient began to sink, and soon died of heart-failure. The dressings were removed soon after death, and the clamps were found securely in place, no secondary hemorrhage having occurred.

It will be seen, then, that this was no ordinary case The record of the temperature shows a regular curve over which it ranged from 99⅕° to 104°. The etiology is exceedingly obscure. Whether the vessel was injured at the time of the blow on the hip, on *March 7th*, is somewhat doubtful; and yet, if the statement of the family and of the boy himself can be admitted in evidence, this certainly seems to have been the beginning of his tumor. Why he should begin to limp on *March 1st* and continue limping until the 7th, the day of the injury, is difficult to understand. The explanation seems to my mind this: The mere attack of subacute rheumatism would account for the lameness, and the blow of his playfellow might rupture the artery, as it lies very close to the bone at this point. The boy's muscle and adipose were not abundant in this locality.

Dr. Keyes writes me the following, for fear he may not be present this evening: "I can only say that at the time I saw the case it was a peculiar one in its clinical aspect—so manifestly tense, fluctuating, inflammatory, even œdematous at and near its obviously pointing spot. The absence of murmur and thrill, with the patient's pallor and fever and sweats, the negative testimony of the aspiratory punctures made before and after I saw the case, the very pronounced relief from inflammatory symptoms after my last puncture, and the fact that the fluid drawn at this puncture contained heaps and clumps and clusters of leucocytes—I think as many leucocytes as red cells—all this, and much of the circumstantial evidence, was so misleading that, although instructed now by the case, I do not feel that the failure to pronounce the tumor a dissecting aneurism at my or your early visits was at all peculiar. I have treated a traumatic aneurism of the gluteal artery in Bellevue Hospital successfully, cutting down boldly upon it, turning out clots, and with some difficulty ligating the vessel. I am not unfamiliar with dissecting aneurism, but I have not seen one behave as did the one in this case, nor have I before seen dissecting aneurism start from the internal pudic artery. I have many times since our operation thought over this case, and I have on such occasions concluded that the course followed was the proper one. A more prolonged operation would certainly have left the patient dead on the couch—which I think he would have been in any case but for the exhibition of brandy by Dr. Lee, and the careful manner in which the doctor managed the ether. Had the boy rallied for a day, I think, starting with the knowledge furnished by the first operation, that the vessel might have been safely ligated with catgut, but I do not believe that such a course would have saved the boy's life. This is the way I look at the case, surgically speaking. Why the vessel gave way in a young boy in the first place, I find it difficult to understand. The local injury must have had something to do with it, but even this seems peculiar, as the pain went before the injury."

Dr. Shaffer, in some remarks, thought "that the case was one of unusual interest to the orthopedic surgeon, as, apart from its intrinsic interest, it furnished another subject for consideration in the differential diagnosis of hip-disease. He remarked that the high temperature, in connection with the existence of a fluctuating swelling, would ordinarily be almost conclusive of abscess. He agreed with Dr. Lee that the ruptured artery was probably atheromatous."

Dr. L. A. Sayre asked "whether the blood-clots removed at the operation had been carefully examined, as he thought, from a review of the symptoms, that pus would probably have been found. He remarked that, arguing from the standpoint of our present knowledge of the case, as furnished by the results, an earlier exploratory incision might have been justifiable and possibly productive of good. He admired the moral courage of the gentlemen concerned in the management of the case, in going ahead and securing the vessel when there was such a temptation to defer operation and treat the case expectantly, rather than assume the responsibility of doing the only thing that could be done that offered any chance for the child's recovery; although by so doing they incurred the risk of being censured by the family and other ignorant persons for performing, in their judgment, an unnecessary operation."

It was difficult for me, as well as for the other gentlemen in the case, to regard this as anything more than a subfascial abscess, and even after the exploratory puncture it was difficult to reach the conclusion that finally pressed itself upon us. As Dr. Lee states, and as Dr. Keyes' remarks state, the whole course was unlike that of dissecting aneurism. I had no difficulty in excluding ostitis of the hip, or synovitis even, when I first saw the case. The signs, the symptoms, all pointed to a periarticular lesion.

I presented the above report to the Orthopedic Section of the New York Academy of Medicine on May 20, 1887, and I am permitted to make use of the discussion which followed on that occasion. Dr. C. C. Lee has at my suggestion written out his remarks, and they are as follows:

"As general surgeons we are all interested in anomalies that lead to errors in diagnosis, and the difficulties that beset this case from the beginning were numerous and complicated. The diathesis of the patient, his antecedents of cardiac disease, his exposure to cold and chilly air before his attack, and the manner of its inception, all pointed to rheumatism. The rapid variations in temperature, the sweats, and increasing exhaustion that followed, soon compelled the abandonment of this theory, and pointed to suppurative changes as the sequence of a periarthritis; while the entire absence of thrill, murmur, or pulsation in the tumor rendered the suspicion of aneurism (which was entertained and discussed at an early stage of the attendance) entirely doubtful.

"Our failure to obtain pus by the numerous aspirations was attributed to our inability to strike the correct spot with the exploring needle. Thus we remained in the dark, although employing every means within our reach, and no correct diagnosis was made until the exploratory punctures that led to the operation which preceded the patient's death.

"If in this we were culpable, we place the case on record in the hope that others may profit by our mistake.

"The cause of death, as has been correctly stated in the paper, seemed to be purely secondary shock from heart-failure; for the boy rallied from the immediate effects of the operation better than we had expected. His consciousness fully returned, he was rather cheerful, and conversed with some members of the family; he took small quantities of milk with vichy and beef-tea, but when, seven or eight hours after the operation, he began to fail in strength, the heart-failure was extremely rapid.

"On all points narrated by Dr. Gibney, supplemented by Dr. Keyes, I find myself in accord, except one, viz.,

causation of the rupture of the artery. To me this seems very obvious.

"In nearly all such cases of cardiac disease in young subjects—double valvular disease with dilatation of the left heart—(most of which are congenital) there is as distinct a tendency to fatty degeneration or atheroma of the arteries as occurs in cases of apoplexy. Granting that this obtained in our patient—which I suspected more than once from the wiry feeling of his radial artery, the rupture of a vessel which is suddenly forced against the unyielding neck of the femur by a sharp compressing blow would seem to need no elaborate explanation. The clinical history is in exact accord with this assumption."

NOTES ON STERILITY.

By JAMES OLIVER, M.B., F.R.S. Edin.,

ASSISTANT PHYSICIAN TO THE HOSPITAL FOR WOMEN, AND HONORARY PHYSICIAN TO THE FARRINGDON GENERAL DISPENSARY, LONDON.

Every occurrence in nature is the result of some previous occurrence, which we have agreed to call its cause, and which in turn determines some other, which we consider its effect. Nothing is accomplished at any time by a sudden act of transition. Nature, so to speak, never executes her workings by fits and starts. Interdependence is avowedly maintained. In the animal kingdom especially are these facts revealed, whether the end attained be one likely to prove beneficial to or exert a prejudicial influence on the species. In the whole organic world change is wont to be gradual; creation and destruction keep pace with each other, and wherever there is life we witness coetaneously a gradual death. In the process of generation the same phenomenon is manifested. Between that state favoring the production of a numerous offspring and that culminating in complete sterility, there exists no distinct line of demarcation. So gradually in fact do the two states glide into each other that we are wholly unable to say where the one ends and the other begins. In the vegetal as well as the animal kingdom we may therefore encounter every degree of fertility.

The reproductive function, no matter how fulfilled, is wrapt in obscurity and full of the greatest complexity, yet from a scientific point of view teems with questions of the deepest interest. Take, for example, the mysterious influence of a first coitus on the progeny resulting from an immediately succeeding sexual congress. Breeders are most careful to avoid contaminating their stock in this way. If a bitch be covered by a dog of inferior breed, the offspring, although begotten thereafter by a dog of known high quality, may evince some traits or markings derived from the former bad cross. A purely bred Arabian chestnut mare was covered by a quagga, the resulting offspring being a hybrid. Some time afterward this same chestnut mare was covered by an Arabian black horse, yet so potent was the influence of the coitus with the quagga that two colts begotten by this cross with the black horse had the hair of the mane, like that of the quagga, short and stiff. The quagga, after the birth of its own immediate progeny, had never had an opportunity of covering the mare again. Here the first coitus affected, in a marked although inexplicable manner, the offspring of the Arabian black horse. The effect of a single coitus may for long afterward continue to exert its influence, and this in cases beyond all doubt. I merely adduce this evidence in support of the tenet which previously I expressed that the whole question of reproduction is not simple, as many would lead us to believe, but one full of complexity. In order, however, that we may have as clear a conception as possible of the multifarious influences at work tending to induce sterility, we must approach the whole subject and attempt to elucidate revealed facts with a mind free from all bias, for in this way alone shall we serve the end of science by encouraging truth. Be it remembered mistakes more commonly result from a defective observation than from ignorance.

In man and the majority of animals perpetuation of the species is maintained by a process of germo-genesis by a coalition and further segmentation of the germinal elements produced by two sexually distinct individuals. It is, to a certain extent, this participation in the act of generation by two parents which hinders us in our investigations regarding those causes which, constantly at work and liable to the greatest variation, act and react directly or indirectly on the reproductive organs. In the case of the male parent all interest actually ceases with the emission of a sperm element, while the mother, on the other hand, not only produces a germinal element, but must retain and nourish, for a more or less definite length of time, the impregnated mass, until, in fact, it shall have reached that state of developmental perfection enabling it to cope with external surroundings.

An inquiry into the causes of sterility must not treat merely with the glands concerned in the production of the germinal elements and the relative affinity of these elements for each other, but deal also with those constitutional conditions which directly or indirectly interfere with the functions of the whole reproductive tract and the competent fulfilment of its requirements. When we remember that the female plays the all-important part—and for a continued length of time—in the production of offspring, it is not astonishing that we should so frequently find authors disposed to attribute the cause of failure in the sexual congress to become fruitful to some occult influence at work on the part of the mother. This admission does not, however, imply a need for the detection of some structural change in the organs of generation in a female who, because she has legitimately indulged in sexual intercourse for years, has never become pregnant. A tendency in this direction, I need hardly add, is too frequently revealed, and simply as a result of defective observation. The alleged alteration in structure has, as a rule, no other than a mere fanciful existence in the mind of the observer himself. We must not, therefore, be too readily carried away by a semblance of brilliant results obtained by a too meddlesome interference, for careful observation teaches us that the good which accrues is, in the majority of cases, the outcome of an enforced sexual rest. In order that any organ of the body shall continue to perform its functions healthily, time must be allowed for the structure to regain its vigor after each period of activity. If sufficient rest be not allowed the function becomes impaired and the structure itself may eventually undergo change, because of a maintained vascular turgescence. An immoderate indulgence in sexual intercourse, or the adoption of an artificial mode of gratifying the passion, tends to induce a state of the genital glands favoring sterility. Under such circumstances conception is likely to happen after a prolonged sexual rest, followed by a moderate indulgence in the act and its legitimate practise. In the human race there are so many factors forever at work in the social life and habits of the individual which thwart us in our endeavors to elucidate questions bearing on the reproductive process, that our chief and reliable information regarding those causes which tend to induce a sterile state must be obtained from those facts afforded us by the whole organic world, whether it be vegetal or animal. Lately I saw a patient who, at the age of thirty-six, had given birth to her first child, and who, although living a marital life for eight years, had never before been pregnant. In this case I found on interrogation that delay in conception was the result of the adoption on the part of the husband of a simple and well-known mode of protection, and this because of a mutual desire on the part of the husband and wife to be free from the cares of a family.

That certain physical states of the organs of generation hinder conception is apparent to everyone; these, however, are manifestly overrated. Never, for example, do we find the lumen of the cervical canal of the uterus

so narrowed in a female otherwise reproductively healthy as to be a fertile cause of sterility. In order that this may receive some credence it may be well for us to consider cursorily the train of events consequent on impregnation in the bird, as throwing some light on the location at which, in the reproductive tract, the sperm and germ-cell meet and coalesce. The egg, after fertilization, becomes coated with a calcareous product, the shell, which serves simply to protect the contained mass from all extraneous injurious influences to which, during the process of incubation, it may chance to be exposed. The secretion of this calcareous incrustation takes place in the lower and somewhat dilated portion of the oviduct, in a part closely analogous with that which in the human female becomes uterus. Occasionally we find eggs extruded by a female bird which have no calcareous covering, the result of a defective fulfilment of functions on the part of the dilated portion of the oviduct. The impregnated mass under such circumstances, enveloped by a simple membranous covering, is liable to be disturbed by influences acting on it from without, and is wholly unfitted for undergoing a natural evolution and thereby reaching maturity. Failure on the part of the oviduct to furnish this calcareous covering must be viewed as a tendency to sterility. Prior to the deposition of a chalky coating the impregnated mass receives an albuminous covering derived from the upper and tortuous part of the oviduct. This being so, the germinal elements, male and female, meet and coalesce somewhere about the free extremity of the Fallopian tube. In man, and all animals with a reproductive tract resembling that of the bird, the germ and sperm-cell commingle in the upper part of the oviduct. So long, therefore, as the lumen of the cervical canal is not unduly contracted, it cannot *per se* offer any very serious obstacle to conception, for the Fallopian tube itself, which naturally admits with difficulty a fine bristle, allows of the easy passage of the spermatozoa to the germ-cell or cells. In all animals the reproductive organs appear to be most highly sensitive, trifling changes in the habits or surroundings of the organism serving in some occult manner to disturb the generative functions. In the majority of such cases which have been observed and noted the dependency seems to be altogether incredible. Animals, for example, tamed and kept in their native country may prove sterile, and this apart from any negligence in the way of food or attention to the general comfort of the animals on the part of those who keep them. Elephants domesticated in their native home, living to a good old age, and evincing no manifestation of physical deterioration, have never been known to couple, yet the generative organs continue active. The character of the food affects markedly the power of procreation. It has been remarked that mares brought up for a long time on dry food are usually sterile. If, however, such mares be turned out to grass, the mere change in food, inappreciable though it may appear to be, renders them eventually fertile. It has been remarked by a competent observer that lions in small travelling menageries are more prolific than those confined in our zoological gardens. Why this should be is difficult to understand. The animals in travelling shows are not better tended nor better fed than those in our gardens, neither have they more room. Here, doubtless, there is some slight cause at work. It is quite possible that the constant variation in surroundings and the perpetual state of excitement of the animals induced by their movement from place to place may account for greater sexual vigor under such circumstances. In some cases, although not invariably, domestication increases fertility, and this apparently, because of a more easy access to food and an abundant supply of the same, the food at the same time being most highly nutritious. Under confinement the functional activity of the organs of generation is not uniformly disturbed in all animals. The lion breeds readily when confined, and produces a greater number of young at a birth than any other member of the same tribe. Impotence occasionally results from domestication, the sexual appetite at the same time continuing unimpaired. The bears in our zoological gardens indulge in sexual intercourse extensively, yet the congress seldom proves fruitful, for they rarely produce young. Male birds, when confined, often lose their characteristic plumage, and yet this manifestation of constitutional change is unassociated with sexual enfeeblment, the reproductive power remaining unimpaired. Sexual passion even may continue in abeyance without apparent reason and without co-relative change in the physical well-being. Absence of sexual desire or feeling does not necessarily imply sterility, for frequently we see women who, experiencing no pleasure whatever during coition, nevertheless conceive and prove even as fertile as those in whom the passion is readily excited. Multifarious and slight are the changes in the life of the animal and its surroundings which may, in some occult and wholly incredible manner, affect the reproductive power. A man and his wife lived in a little village on the east coast of Scotland for ten years, and during this time the wife, although enjoying full marital rite, never became pregnant. Circumstances compelled them to change their habitance, their future home being chosen in the South of England, the climate of which was much less severe than that of Scotland. In this case the mere change was sufficient to determine fecundity, the woman thereafter giving birth to several children.

Every male and female mated is not fertile, yet separately each may be highly endowed with the power of procreation ; for this same male and same female, mated with another female and another male respectively, may prove eminently fertile and produce a numerous offspring. The germ and sperm-cell may meet and coalesce ; in order, however, that an uninterrupted segmentation may be evolved, they must produce by their union, not a state of equilibration, but a state of molecular disturbance. If true molecular waves, radiating from the two primordial elements, are too closely allied to each other, they tend to induce a state of equilibrium, all vital reaction immediately ceases, and no further evolutional change becomes possible.

By adding light to light we can produce darkness ; in like manner, we can produce silence by adding sound to sound. If two waves, equal in every respect and travelling in opposite directions, impinge against each other in their full extent, the forces counterbalance each other exactly and produce total rest. The fault causal of sterility, under such circumstances, is assignable to neither parent, but to both. The elements produced by each are, in reality, too closely analogous to each other. Placed even under the most favorable circumstances they fail when they commingle to act and react upon each other so as to produce that amount of instability requisite for further segmentation and the production of an independent being. This form of sterility is the result of a sexual incompatibility, the reproductive elements derived from the separate beings lacking that dissimilarity needful for developmental change.

In man we find abundant proof of the existence of this anomalous phenomenon as well as in animals. Lately I saw a patient who, during fifteen years of marital life with a first husband, never became pregnant, yet coition was fully accomplished and completed. At the age of forty this female married a second time, and soon afterward conceived and gave birth to her first child. The same fact has been noted frequently in the case of other animals. A bitch is covered by a dog of known sexual activity several times, under the most advantageous circumstances, yet fails to conceive. If, however, the dog be changed, a future congress proves fertile, and the bitch gives birth to several pups. Every attempt to cover the bitch by the first dog proves equally ineffectual, and this because of a mere sexual incompatibility. A cart mare, in like manner, is covered by a

blood horse, yet no progeny results; if, however, the same mare be covered by a cart stallion the congress proves fruitful, and a fully mature colt or filly is the result. With plants we witness a like parallel, and this even in the case of grafting. Certain plants may be grafted on others readily. The currant, for example, may be grafted on the gooseberry; the gooseberry in turn, however, cannot be grafted on the currant. This mode of reciprocal behavior is strange, for we fail to detect any real structural difference between the nurturer and the nourished, or any reason whatever for this apparent incongruity. Both male and female may be equally fertile, yet because of the existence of some sexual incompatibility when mated together, they are totally sterile.

Frequently we see women who apparently exhaust their full reproductive energy in giving birth to one child, as they never afterward conceive. The individual may note no change in her general health, the sexual functions may be as thoroughly maintained, and the congress may be as completely effected as before, yet the sterile state prevails. Barrenness is wholly independent of change in the general health of the individual, and is frequently remarked as an association of excess of size and great luxuriance. In plants very high nutrition often lessens materially, or may even completely arrest, the reproductive power. Many of our trees which become luxurious, yet bear flowers or fruit seldom, are capable, in some cases, of being made more productive by cutting the roots, and so lessening the amount of nutrition. I have commonly observed that women who tend to lay on fat rapidly are apt to become barren. In the majority of such cases the adipose tendency is a morbid condition, and sterility is a mere concomitant depending on the condition inducing obesity.

As I have already remarked, the energy expended by the male in the process of perpetuating the species is comparatively slight compared with that demanded of the female. We shall, therefore, often find that sterility depends upon a failure on the part of the mother to supply that amount of nourishment requisite for those evolutional changes consequent on impregnation. The young begotten of animals under confinement often die early or are even born dead or badly formed.

As a rule, sterility is a physiological co-association of functional activity of the mammary glands. This depends upon the fact that, at least for a time, these glands continue to withdraw from the mother that amount of nourishment which otherwise would have been devoted to the maintenance of the reproductive activity. In the case of the cow we witness a perversion of this law of nature by habitual interference on the part of man, the mammary glands, through constant use, being made to secrete milk quite independently of the reproductive system.

Women who marry early may for a time give birth to children too rapidly, but eventually the reproductive energy wanes and a state of sterility is induced, the general health of the individual becoming impaired, or evincing, it may be, no sign of deterioration.

Prostitutes, so long as they cohabit with a variety of males, are sterile, yet no special precaution is adopted to prevent conception. Protection doubtless depends upon the fact that the various germinal elements tend to counteract each other. In the case of plants a parallelism has been noted. If the pollen from a flower be placed on the stigma of another flower, and this same stigma be fertilized soon after by pollen obtained from a stamen of its own flower, the influence of the first pollen is completely destroyed by the last applied, and no fertilization results. Bees and ants teach us that to a certain extent a life of ease and idleness is that most favorable for reproduction, while a life of great activity predisposes to barrenness. According to the amount of nourishment the larva receives it develops into a small sterile insect or the large fertile female. It does not, of course, follow that every animal will evince an activity of the reproductive organs commensurate with the pabulum it is capable of using. Other things being equal, plenty of food with a life of idleness are eminently favorable for the process of generation. That race which is idle physically as well as mentally and at the same time is well fed is likely to prove more fertile than a race living under directly opposite circumstances. The servants of races cruelly treated and made to undergo the most severe physical exertion either prove totally barren or at least less prolific than those more advantageously placed, living a life of comparative freedom. Twins and triplets probably indicate a higher state of reproductive activity consequent on a large supply of easily assimilable food. The Kaffir women, who live chiefly upon flesh and milk, are most prolific and give birth almost as frequently to twins as single children. The higher education of women is doubtless detrimental to the race of man, tending, as it must, to engender a state of sterility, or, what is worse, to the production of a race with evidences of great constitutional enfeeblement.

A SMALL POINT WORTH KNOWING.

By LUTE L. VON WEDEKIND, M.D.,

SENIOR OF STAFF, CHAMBERS STREET HOSPITAL.

In presenting this paper to the medical profession, I am, for the present, constrained to disclaim the positive discovery of the *small point* and its use, herewith submitted. If there be another who has applied and published results in reference to this point, I cheerfully allow him the honor to which he is entitled. Until such an one be found this article may simply be regarded as a record of personal observations; interesting, perhaps, to those who may already know and practise what is here stated, but of positive benefit to those who as yet may be unacquainted with it.

Simplicity of application, infallibility with regard to results, and great practical usefulness in forming a correct and prompt diagnosis of a given case, are what I claim to be the important points with reference to this subject.

By simply pressing on the supraorbital notches with a steadily increasing force, you may, with a certainty of success, detect a malingerer; bring an unconscious alcoholic to his senses, and thus differentiate on the spot between alcoholic and other comas; cause cessation of hysterical convulsions, and in many instances quiet violent alcoholic delirium.

The best way of applying this test is: When the patient is in the recumbent position, the physician, standing at the head of the cot, or kneeling when the patient is on the ground, fixes the tips of the thumbs over the supraorbital notches, as above described, never minding the occasional yell or struggle, pressing steadily, gradually increasing the force, and in half a minute or a minute the result is accomplished.

In a varied and extensive ambulance service, extending over eight months' continuance, I have applied this test so frequently and, as my statistics will show, with such marked and remarkable success, that I feel constrained to publish my results.

To the physician in private practice it may be of comparatively little use; but to such as are in the hospital service, especially in the ambulance department, or to those employed in the army and navy, or elsewhere where large bodies of men are at work, and where malingering and alcoholism are common, it will be of great value.

The frequency with which ambulances are summoned to alcoholics and malingerers renders this test doubly serviceable, assisting the physician, first, in the rapidity, and, secondly, in the correctness of his diagnosis. Moreover, it is a remedy always ready, always reliable, and always productive of satisfactory results.

For let it be remembered that if the application of this test *fail* in obtaining the desired result, the physician may *rest assured*, and the subjoined column of cases seals this assurance, there is something more than simple

alcoholism, or those other forms mentioned, in the case. And so, on the other hand, what a comfort it is for him to know that, after the heroic and protracted efforts of the police and other parties have failed, he can step in and in a moment have the patient on his feet. Into what confidence and esteem of the astonished lookers-on it places him at once.

During my ambulance service at this hospital, the following particulars may be mentioned: Out of 1,620 ambulance calls, 213 were to alcoholics; 26 to malingerers; 18 to hysteria cases; and 28 to delirium tremens.

Of the 213 above mentioned, 137 were comatose, the police and friends being utterly unable to arouse them, and this treatment brought 128 of the 137 to consciousness. Of the cases where no result was obtained, 5 were, besides alcoholism, suffering from cerebral concussion, 2 fracture of the base of the skull, 1 uræmic coma, and 1 syncope from valvular heart trouble.

In the cases of hysteria I had absolute success; no one case failed to respond, and the same with malingerers. Nine of the delirium tremens quieted down and spoke rationally; in the remainder I had varying degrees of success; some becoming more quiet, while in others but little change was noticed.

Illustrating this point, I will cite a few of the many interesting cases:

The ambulance was summoned by the police to a case on the North River front, supposed to be dying. Upon arrival I found a man, comatose, having a few lacerated wounds of the scalp and considerable blood on his face. The police had tried hard to arouse him, but failed. After having ascertained that the man suffered no fracture of the skull, I proceeded to arouse him by this method, succeeding in about a minute. His breath smelled strongly of liquor, and he admitted having been drinking hard for the five or six days previous. He sat up, had his head dressed, and walked to the ambulance, which took him to the station-house.

A. G——, aged twenty-four, a native of the United States, was found by the police lying on the sidewalk, claiming to have fallen down the cellar of an unfinished house. Upon the arrival of the ambulance, this man claimed that he could not move either his legs or arms, and that he was gradually losing sensation. With the greatest care he was placed upon the stretcher and slowly driven to the hospital. We found no other indications of spinal concussion or fracture, and became suspicious of a malingerer. Pressure over the supraorbitals was resorted to and kept up for about a minute, when the patient, raising his arms, grasped my hands and removed them. Being satisfied of the diagnosis, we ordered him to get up, which he refused to do, claiming complete disability. He had to be forced out of bed, and then, seeing that the "game was up," became very abusive. His idea was to sue for damages, having previously claimed that it was the builder's fault, he not taking the necessary precautions to insure the safety of passers-by.

A. B——, aged twenty-four, has been brought to this hospital quite frequently for syncope. It was her practice, until discovered, to faint somewhere in our district whenever she was out of funds. The last time I found her in a street-car, and, suspecting her to be a malingerer, I applied this test, which worked like a charm. I told her that she had "played off" too often, and refused to take her. I saw by the papers next day that she continued to ride until in the district of a neighboring hospital, when she again fainted, and was carried away by the ambulance. She has since admitted her deception.

J. G——, aged thirty-nine, printer, has been brought to this hospital at least six times within the past eight months, for epilepsy. During one of his attacks I tried this pressure, to see if there could be any result. In about one minute the man sat up, saying: "Well, Doc., I could not hold out any longer." I had not the remotest idea that he was malingering, as he had the regular convulsions, frothing at the mouth, and biting his tongue or lips, which is usually sufficient for our diagnosis. He claims to have "worked" with great success all the hospitals, usually having his fit when out of funds.

The cases of hysteria have all acted in exactly the same way, answering to the test in from one to two minutes at most, but usually in from fifteen to thirty seconds.

G. E. B——, aged nineteen, was suffering from hysteria in the passage-way to the Brooklyn Bridge. For twenty minutes the police tried to quiet the convulsion, but failed, and then summoned the ambulance. One minute after arrival I had the boy on his feet, perfectly quiet and exceedingly anxious to get away. He went.

In the cases of delirium tremens I have not been so markedly successful; for but few of the cases answered promptly, and many not at all.

C. E——, aged twenty, was brought in by the police, suffering violent delirium. It required three men to hold him down. I applied pressure over the supraorbitals for some forty seconds, when the patient became quiet and submitted to a hypodermic without question. I have had some four or five similar cases, but not enough to claim infallibility for this method in this class of cases. Dr. E. B. Dench, Dr. G. Swinburne, and Dr. P. T. Kimball, of this staff, have tried this in similar cases, with the same degree of success.

I have tried it in forty-seven cases where no result was obtained, and where something more serious than alcoholism or malingering was suspected.

Of these cases 26 were cerebral concussion; 9 fracture of the base of the skull (diagnosis confirmed at autopsy); 4 cerebral hemorrhage; 6 uræmic coma; and 2 simple depressed fracture of the skull. These cases are mentioned as proof of what is above stated. Where no result is obtained, there you may look for some intracranial lesion, or other cause of coma.

Epithelioma of the Umbilicus.—Dr. Barraud describes the case of a patient, forty years of age, who was admitted into the Hôtel Dieu on February 8th for a tumor of the umbilicus. No hereditary antecedent could be discovered. She married when twenty-eight years of age, but never had any children, and had never been ill. Seven months previously, while taking a bath, she noticed a little scab over the umbilicus. On removing this she noticed a small swelling, about the size of a lentil, of a wine-red color, and not ulcerated. She did not pay much attention to it until, in the course of two months, she remarked that the tumor had increased in size. She then consulted a medical man, who applied the actual cautery and dressed it with iodoform. Soon after, the tumor became rapidly bigger, and, three weeks since, it ulcerated and exuded small quantities of blood. The umbilical cicatrix was entirely invaded by a tumor about the size of a penny-piece, circular in outline, and projecting. The bottom of the ulceration was covered with granulations, and exuded a puriform, but not offensive, discharge. The tumor was firm and elastic to the touch, and could not be reduced. It was situated on a zone of induration, extending over a space about the size of the palm of the hand, and it appeared to send ramifications toward the abdominal cavity. The tumor was fixed in a vertical direction, but admitted of some lateral movement. No enlarged glands could be found. The general health of the patient was good. On examination the tumor proved to be a cylindrical epithelioma. The growth was removed by means of two curved incisions, meeting above and below the umbilicus. The mesentery was not involved, and no adhesions had formed. After removal, the lips of the wound were brought together and retained in position by means of deep sutures of silver wire and superficial horsehair sutures. Recovery was rapid and complete, and the patient was soon able to leave the hospital, provided with an abdominal belt as a support to the cicatrix.—*The London Medical Record*, July 15, 1887.

Clinical Department.

COMPLETE DISLOCATION OF THE EYEBALL.

Dr. M. B. Sullivan, of Dover, N. H., reports the following rare case. "On the evening of July 16th I was called to attend Daniel F—— on account of an injury to his eye. I arrived at his boarding-place and found a young man, about twenty-two years of age, recently arrived from Ireland, and the appearance he presented eclipses anything I have ever seen. He was crossing the kitchen floor, slipped on a lemon-seed, and pitched forward toward the stove, in one of the covers of which was left a cast-iron lifter in an upright position; he struck on this just over the eyeball, and as it was driven into the orbital cavity his eye popped out, and when I saw him it was sticking directly out, with both upper and under lids completely inverted behind the eyeball. I applied cocaine solution, six per cent., and finding I could not get reliable assistance in the house, sent for Dr. J. R. Ham. I succeeded in everting the lower lid, but with much difficulty, with a pair of Charrière forceps, locked them, and had them held, and with another pair everted the upper lid, when the eye slipped instantly into place. This was a genuine case of dislocation of the eyeball, but I find the works on surgery say very little about them. The vision is now perfect, and the conjunctivitis which followed has entirely subsided. The strain upon the optic nerve was not over forty-five minutes."

A REMEDY FOR VOMITING IN PHTHISIS.

Dr. A. D. Bundy, of St. Ansgar, Ia., writes: "In advanced cases of phthisis pulmonalis, coughing ending in vomiting, so that the food is often ejected from the stomach and nutrition is greatly interfered with, is a condition I have found difficult to relieve. In a recent case the trouble was promptly controlled by means of the following solution: Cocaine hydrochlo., gr. x.; eucalyptus, gtt. xxx.; alcohol dil., f. ʒ j. A common hand-atomizer was used to spray the throat three times a day, the patient being directed to inspire as the bulb was compressed."

ONE OF THE EMERGENCIES OF COUNTRY PRACTICE.

Dr. Charles Emfield, of Jefferson, Ia., relates the following case as illustrative of the emergencies with which the country doctor has occasionally to deal: "I was called during the winter to a farm-house some fourteen miles from this place, where I found a woman forty-six years of age in an extremely anæmic condition from uterine hemorrhage that had been almost constant for a month. She had been prescribed for without avail. I found the uterus enlarged to correspond with the fourth or fifth month of pregnancy, and the os uteri closed and its tissues quite firm. From the history of the case I diagnosed an enlarging uterus from retained products of conception, and as it was evident that there was no time to lose I proposed emptying the uterus, to which the husband readily consented. I inserted a large sponge-tent on the following day, which by midnight had expanded and softened the uterine neck, but had also induced so much prostration that several hypodermics of ether and brandy were required to keep my patient from sinking before I could attend to the local condition. With the patient under ether we carried her to a table, my assistants being the husband and a neighbor, and as a moral stimulus I had about me, cuddled down on the floor, some eight or nine children. On inserting my hand into the uterus I reached a soft, friable substance. The organ itself had expanded on the admission of air, and I feared that I would have difficulty in exciting contraction for the arrest of commencing hemorrhage. I rapidly removed the contents of the uterus, which I found to consist of uterine hydatids and clots, enough to fill a small wash-basin. Bimanual excitation brought about firm contraction, and after a thorough intra-uterine irrigation the patient was put to bed. She promptly recovered with the aid of daily irrigations of the uterine cavity."

MEASLES—ANURIA—CONVULSIONS—DEATH.

Dr. A. G. Browning, of Maysville, Ky., reports the case of a girl, nine years of age, whom he saw with Dr. J. T. Strode. The child had always been healthy, and lived in healthful surroundings. She was convalescent from measles, and had been about the house for a week or ten days. At a later period than is usual in measles, she had had a sharp attack of diarrhœa, with mild dysenteric symptoms. This yielded readily, and she was again doing well, when there came an attack of catarrhal croup. When she recovered from this, a decrease in the quantity of urine voided was noticed, but there was no other disturbance of moment. The usual routine mild correctives had been given, but without improvement. More energetic measures failed, and when Dr. Browning first saw the case no urine had been passed for three days and nights, the occasional use of the catheter showing the bladder to be empty. There had, however, been no developed constitutional symptoms. The urine had not been examined previously, and the suppression, when it came, was so complete that not a drop could be obtained for examination.

"The pulse was between 100 and 120, small and without force; temperature, only once taken, 99°; respiration, 16; some sighing, but no cyanosis; squinting, with right lateral eversion of both globes; oscillation of pupils; some subsultus; intelligence good. The abdomen was retracted, and there was a shrivelled, old look of all the muscular structure. No heart-trouble. Careful examination developed only slight soreness in lumbar region. There seemed nothing marked but the suppression, and the impending results. Warm baths were ordered, and local fomentations were employed in the intervals between the baths. Pilocarpine was given liberally, and this failing, it was in time replaced by digitalis, spirits of nitre, and acetate of ammonia, alternating with calomel. But nothing did any good, one convulsion succeeded another, despite repeated doses of chloral by the rectum, and the child finally died in convulsions, no coma having occurred at any time. Five minutes before death the patient had feebly, but rationally, replied to a question."

Dr. Browning continues: "Was all this the logical sequence of measles, in the sense that the same too often is of scarlatina? Here was, seemingly, a nephritis, or, if not strictly such, that catarrhal condition of the urinary tubes almost inseparable from it. This sequel was, as regards its severity, obstinacy, and result, certainly so very rare with me as to be phenomenal. Nor do I find that others have encountered it—that there is any allusion, in the literature at my command, to nephritis and its results as a probability after measles. Not that we have no urinary troubles after measles. They are, however, as a rule, void of special significance, and may be safely regarded as indicating only slight functional disturbance.

"Or, the conditions remaining the same, was the dysentery the prime factor in causation? I don't think so; there was not enough of it, for the dysentery present was scarcely worthy the name. True, of all the solid viscera, the kidney is as frequently involved in dysentery as any other. But this occurs to the extent here given only when the affection is protracted, severe, and accompanied by putrid stools, more or less copious (Zimmerman, 'Sydenham Society Reports'). The reverse of all this obtained in the case, as remarked. Measles may have had nothing to do with it; it isn't plain to me that dysentery had more.

"My search for a way out of all this has revealed, or recalled, one fact, at least—how very little those who know have told us in books about suppression of urine. It is only a symptom, of course, but one, as I have just had occasion to know, with something very real behind it, and it is a symptom which parsley and melon-seed tea will not every time relieve."

EPISTAXIS, ASSOCIATED WITH HYPERTROPHY OF THE TONSILS.

Dr R. W. Erwin, of Bay City, Mich., writes that he has found epistaxis to occur frequently in cases of hypertrophy of the tonsils.

"The hemorrhage is due to continuous pressure upon the veins of the neck, producing chronic engorgement above, with, perhaps, alteration in the walls of the blood-vessels. My attention was first called to the subject a few years ago, by a case of frequent and alarming hemorrhages in a child four to six years of age, in whom the tonsils were enlarged so much as to slightly impair the hearing. The child snored at night, and was acquiring a deformity of the chest and shoulders. I was afraid to perform abscission on account of the hemorrhage, though no history of hemorrhagic tendency existed, and I delayed the operation more than a year, doing all I could in the meantime to build up the general health.

"The growth of the child was apparently arrested in a great measure. Finally I removed the greater part of one tonsil, hoping that good would follow. There was immediate relief from the snoring in sleep, with complete and permanent cessation of the nose-bleed. The general health was rapidly restored and has continued good. Within a month a similar case has come under observation. It is possible that the greater tendency to hemorrhage in youth is in part due to the hypertrophy present in this period of life."

Progress of Medical Science.

Dermatitis Gangrenosa Infantum.—At a recent meeting of the Royal Medical and Chirurgical Society (*The Lancet*) Dr. Radcliffe Crocker read a paper on "Dermatitis Gangrenosa Infantum." Four groups of cases were described. In the first there was no evidence of varicella antecedent to the gangrenous or ulcerating eruptions, and in most it was distinctly negatived. In the second group are cases in which varicella has preceded the sloughs or ulcers, which either developed immediately upon the varicella pustule or occurred as a sequela beginning in independent lesions. In the third group vaccination was the immediate antecedent. In the fourth group are placed certain cases of local gangrene resembling cancrum oris; but the individual lesions began in exactly the same way as the independent eruption which followed varicella, and there was a tendency to generalization, or, at all events, to extension beyond the region in which it started in some of the cases. A general account of the disease was drawn up from an analysis of the preceding and other cases, and it was shown that there is a great difference in the severity of the eruption. In some the gangrenous patches were so numerous and extensive as to lead to the death of the patient in a few days, while at the other end of the chain are cases of so mild a character that there were only superficially ulcerating pustules, which came out in crops, thus protracting the disease as a whole for a considerable time, and generally accompanied by intense pruritus; these milder cases appear to correspond with Mr. Hutchinson's varicella prurigo. Between the two extremes are cases of all grades of severity. Comparison was made between the local and general gangrenous eruptions, and, among other things in common, it was shown that they both attack girls more than boys, and occur at about the same ages. The conclusions arrived at were—that the gangrenous eruptions are pathological accidents, so to speak, which in young children, especially when of tubercular constitution, might supervene upon any pustular eruption, although no doubt such a condition is much more common after varicella. Secondly, that the determining factor is probably a micro-organism derived from without, though cultivation and inoculation experiments could alone prove the truth of this theory. Thirdly, that the initial lesions, both of the local and general gangrenous eruptions, present the same characters. Mr. Jonathan Hutchinson said that he never doubted that other eruptions than vaccinia and varicella could be followed by gangrenous changes. The various specific animal poisons had the power of altering the condition of the patient, and rendering him liable to gangrene of the skin and other parts. He had seen many cases of cancrum oris in children who were in excellent health till the measles, or other specific fever, had overtaken them. There were cases also in which no known antecedent cause could be made out—neither syphilis, nor scarlet fever, nor vaccinia or varicella, etc. He distrusted the view that tuberculosis as a constitutional tendency was liable to set up gangrene of the skin. He thought this was very highly improbable. He thought that we must receive with caution the statement that no evidence existed of the previous occurrence of varicella, for it may be easily overlooked, having occurred in a sporadic form. Infection may occur in individual pustules which are not of varicellar origin; these are not extensive and not symmetrical, but irregular in distribution, and resulting from injury are succeeded by the formation of pus and absorption of the same.

Diabetes Mellitus in Early Life.—Dr. McCall Anderson reports two cases of diabetes mellitus occurring in young children. In one case the age was two years and three weeks, when the father consulted the author because for about six weeks the child was noticed to droop; there was loss of appetite, with constant thirst and progressive loss of flesh and strength. The urine contained a large quantity of sugar, its specific gravity being 1.038. Two days after the father's visit the child died. The second case was that of a little girl, aged two and a half years; she had always enjoyed good health, until on January 1, 1884, when she had a fall, alighting upon her hands, but did not seem to hurt herself. The following day, and more or less thereafter, she suffered from the most intense thirst, with a tendency to coldness, lividity, and collapse. When seen by the author, on January 8th, there was evident emaciation, and the temperature was only 95°. The urine was intensely acid, specific gravity 1.037, containing a trace of albumen, and a large quantity of sugar. Granules of morphia (one-one-hundredth of a grain) were given, and ordered to be cautiously pushed. The child gradually sank, and died on the afternoon of January 9th, only nine days from the first commencement of symptoms. An autopsy was made, but nothing was found with the exception of slight anæmia of the brain, and some fatty change in the renal epithelium, such as might be accounted for by the intese diuresis.—*Glasgow Medical Journal.*

Casein as an Emulsive of Castor-oil.—Dr. de Gassicourt calls attention to the facility with which the casein of milk emulsifies castor-oil. For this purpose the casein must be quite pure, and a little bicarbonate of sodium and powdered sugar should be added. He suggests the following formula as having the advantage of masking the taste of the oil without interfering with its effects: Casein (with soda and sugar), q.s.; castor-oil, 15 parts; laurel water, 5 parts; and distilled water, 100 parts.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 27, 1887.

A CONTRIBUTION TO THE STUDY OF GRAVES' DISEASE.

IN a classical case of Graves' disease we have presented three principal symptoms—exophthalmos, palpitation of the heart, and enlargement of the thyroid gland. But, as is the case in most diseases, and especially in those of the nervous system, it is comparatively rare to meet with typical cases of the affection, and irregular forms largely predominate. We may, however, distinguish three principal aberrant varieties. In the first we have palpitation and exophthalmos without any appreciable enlargement of the thyroid. In the second form palpitation coexists with enlarged thyroid, but the exophthalmos is absent. And finally, in the third variety we find neither exophthalmos nor protrusion of the thyroid gland, but simply a rapid and irregular action of the heart, combined at times with a trembling which may be of the hands alone or may be generalized.

At the recent Congress of Greek Physicians, held at Athens, in April of this year (ΓΑΛΗΝΟΣ, May 23, 1887), Dr. Katsaras described a case seen by him in consultation, which he regarded as one of Graves' disease, illustrating a fourth irregular form of the affection. The patient was a man, sixty years of age, who had for about a year past noticed a protrusion of the eyeballs. The probable cause of the affection was referred to a mental shock. The exophthalmos increased as time went on, but it was the only symptom of which the patient complained. There was no enlargement of the thyroid gland, the heart was regular in its action, and the pulse-rate was not increased. The other occasional symptoms of the disease, such as diarrhœa, dyspnœa, insomnia, etc., were also absent. Despite the paucity of the clinical signs, however, the author was led to make the diagnosis of Graves' disease by reason of the existence of the dissociation of the movements of the upper lid from those of the eyeball, which, following von Graefe, he regarded as a pathognomonic symptom of this affection.

Apart from its clinical interest, the author thought that the case was important as being opposed to the prevalent theory of the nature of Graves' disease. For it is obvious that there could be neither irritation of the sympathetic nor paralysis of the pneumogastric nerve without the results of such condition being manifested in increased rapidity of the cardiac pulsations.

There would seem, however, to be room for doubt as to the correctness of the diagnosis in the case reported. In the first place, the affection is not common in men, and secondly, it is extremely rare in individuals of such an advanced age. The symptom of von Graefe, moreover, is by many authorities not regarded as at all pathognomonic of exophthalmic goitre, for it has been observed to disappear while the other symptoms of the disease remained unchanged. Nevertheless the case is a suggestive one, and might profitably be studied more in detail than has been done by the author in his paper.

IODIDE OF POTASSIUM IN THE BRONCHO-PNEUMONIA OF CHILDREN.

THE expectant plan, now most commonly employed in the treatment of catarrhal pneumonia, is certainly not the ideal method for the cure of this affection, to judge from the high rate of mortality attendant upon it. Yet it is the one generally recommended by writers upon children's diseases, and, indeed, seems to give about as good results as most of the alleged specific methods proposed from time to time by various therapeutic enthusiasts.

In the *Bulletin Général de Thérapeutique* of June 30, 1887, Dr. Zinis, of Athens, writes concerning the value of potassium iodide in certain cases of this affection. He has found it, in doses of from 8 to 23 grains *per diem*, according to the age, to reduce the temperature 3° or 4°, to soften the cough, to facilitate expectoration, and to reduce the frequency of the respirations very noticeably. He thinks that the course of the disease is materially shortened, and that convalescence, when once established, is more rapid. The best results are obtained when the remedy is given at the very outset of the disease, and when the malady is of an acute sthenic form. In the broncho-pneumonias secondary to measles or whooping-cough, or in those occurring in weak or cachectic children, the remedy has given but indifferent results in the author's experience. Its effects are also more favorable, he states, in children over one year of age. In addition to the internal use of iodide of potassium, the writer employed dry cups and flying blisters in certain of the cases in which these external remedies seemed indicated.

EXHIBITIONISTS.

PROFESSOR KRAFFT-EBING, in his work entitled "Psychopathia Sexualis," divides the sexual psychoses into (1) paradoxical sexual feeling, occurring in children and the aged; (2) anæsthesia sexualis; (3) hyperæsthesia, and (4) paræsthesia sexualis. Under the last head, which includes what are generally known as sexual perversions, he describes "lustmord," active and passive flagellation, statuenschänder, and the exhibitionists. He mentions other forms, but we are concerned only in showing that the "exhibitionisten" are distinctly recognized pathological cases.

In a recent lecture by M. Brouardel (*Gazette des Hôpitaux*, May 14, 1887), exhibitionists are described as forming a peculiar type of sexual paræsthesia, to which Professor Lasègne was the first to call attention.

From the somewhat meagre descriptions by the foregoing writers, it seems that the crime or disease is not much observed in France or Germany.

However this may be, it is an important fact that "exhibitionists" are very numerous in New York City. Few families can have lived here long without learning this. The persons who indulge in the extraordinary and disgusting perversion are generally men of middle age, or at least not young; they are often dressed like gentlemen. In the exposures, as is always the case, there is no erection or apparent sexual excitement of the individual, and the act is done not to solicit favors, but to gratify a morbid sexual feeling. The omnibuses, the streets where much shopping is done and women are congregated, and the parks are the places chosen. Of course, the indulgence is a tolerably safe one, for no woman cares for the publicity entailed by causing an arrest. Yet the horror and disgust which the performances of these human monstrosities cause must be very great, and it would not be impossible to diminish greatly the evil which has reached unpleasant proportions. For while the "exhibitionisten" are diseased creatures, they must be treated as responsible; and, besides, there can be no doubt that a certain proportion of them are really indulging only in a morbid and criminal habit.

We do not ask for a letter from Mayor Hewitt on this matter, but certainly the police of New York might do better than they have done in suppressing the vice.

NEW REMEDIES FOR THE RELIEF OF MORPHIA CRAVING.

Dr. Oscar Jennings (*The Lancet*, June 25, 1887) announces the discovery of certain drugs which, he says, will enable any morphia *habitué* earnestly desirous of leaving off his intemperance to carry the process of weaning to a successful issue. All morphia *habitués* have from time to time a maudlin, hysterical desire to give up the practice, but this vanishes at the first feeling of discomfort. For such cases there can be no suppression without restraint, and a result so obtained is very unsafe for the future. By the help of sparteine and nitro-glycerine, however, we are told that the patient can get relief from his craving until the system has accommodated itself to the absence of morphia. The mode of action of the drugs mentioned is as follows: Professor Ball and Dr. Jennings have shown that the heart in morphinomania is in a very depressed state, and that there is a general ischæmia of the circulation. Morphine relieves this, and with it the morbid craving. But sparteine and nitro-glycerine do the same, as shown by sphygmographic tracings.

"The morphia craving," says Dr. Jennings, "is a complex suffering, at the same time cerebral and peripheral, each factor of which can be relieved by appropriate treatment. The organic distress may be soothed by sparteine, which recovers the heart in the same way as a hypodermic injection of morphia. The cerebral craving (or yearning), often the more painful of the two, corresponds to a want of habitual congestion. This can be arrested by nitro-glycerine, which gives rise to the same kind of sensation in the morphia *habitué* deprived of his stimulant as the hypodermic injection. It acts probably by inhibition *à distance* rather than by essential sedation of the nervous centres."

There have been many remedies for the morphia habit, from cinchona bark and Scotch oats to cocaine. All have been, more or less, cardiac and brain stimulants, and it is not easy to understand why sparteine and glonoin should act with any special efficiency. Certain it is that there is no specific for the opium habit.

THE WARD'S ISLAND INSANE ASYLUM ABUSES.

After a very thorough and impartial examination by the Committee of the State Board of Charities into the abuses of the Ward's Island Insane Asylum, a just verdict of guilty has been rendered. Although the medical superintendent and staff are not implicated in the decision, the other authorities are very properly blamed for the bad and innutritious food furnished and the questionable fitness of the ward attendants. Common humanity and public sentiment call for a speedy and radical reform in the care of the pauper insane at this institution, and it remains to be seen if sufficient influence can be brought to bear upon the Commissioners of Charities and Correction to compel them to heed the straightforward and suggestive recommendations of the Committee. The ventilation which the subject has had in the daily press will probably lead to this desirable result.

In regard to the food furnished the patients the Committee says:

"The testimony is undisputed and cumulative, proving conclusively that the dietary is insufficient in variety and nutritious qualities. The bread is good, but the cooking in other respects is shown to be bad. This condition of things is wrong and shameful."

We wonder if the same cannot be said of similar public and private institutions in this city and elsewhere. If we judge from the reports of patients, Bellevue Hospital is notoriously at fault in this respect. But, of course, sick people have no right to decent cooking, and for charity's sake they should say nothing. If the meat is tough it is the fault of their teeth, if the same food is tainted it may be subjectively due to perverted appetites.

Aside from this, what a sorry state of affairs is evident from the statement of the Committee, that the majority of the male attendants were bartenders before they were thus appointed! One witness testified that many of the applicants for the job of attendant were "apparently drinking men, and half-way tramps, you may say, that would be out of a place, and they would come along and apply for this." During the year 1886 eighty attendants were dismissed for cause, exclusive of those resigned or honorably discharged, and inclusive of twenty-three dismissed for intoxication, three intoxicated while on duty in the ward, and five for striking patients.

The report further says: "The circumstantial evidence removes all doubts that there are numerous and continued injuries and indignities inflicted upon the patients by the attendants in the asylum. Overworked, irritable, and ignorant attendants are placed in positions of absolute and exclusive control of badly crowded and excited patients, without appeal or remedy except on unverified reports to absent medical authorities. Each of the medical officers who were examined testified to several acts of violence, by attendants upon patients, which had been witnessed by himself. According to the records of the asylum there were, between October 16,

1883, and June 27, 1887, thirty-one cases of actual violence committed by attendants upon patients, including kicking, striking, and slapping; one case being for slapping one patient by two attendants at one time, witnessed by an assistant physician; another case being for undue violence in handling a patient, witnessed by two assistant physicians; and another case being for both kicking and striking one patient by three attendants at one time, witnessed by two assistant physicians."

It is very obvious that the trouble all lies in the small pay allowed attendants and the lack of room in the asylum building. The Committee very properly suggests that the Board of Charities should immediately have proper plans prepared, and that the Board of Apportionment should supply the necessary money to make the city farm at Central Islip ready to relieve the crowded asylum, the buildings to be on the cottage farm; that healthy and cheerful rooms for patients and attendants, better food, schools for patients and attendants, better attendants and more of them, be provided on Ward's Island. These are measures of provisional relief. For permanent relief it is recommended either that a board of trustees—men and women—appointed by and responsible to the Mayor, be put in charge of the insane asylums; or, better, that one independent commissioner, similarly appointed, shall have entire charge of them, in which cases the Department of Charities might be split into four single-headed departments, governing (1) insane asylums, (2) institutions for children, (3) hospitals and almshouses, (4) prisons. The State Board is advised to memorialize the Legislature if the city fails to provide the proper provisional and permanent relief.

We shall anxiously watch the effect of this investigation upon the action of the Commissioners. The necessity is urgent and immediate, and there can be no excuse for overlooking it save the old one of political expediency. The people are right on the question. Now it remains to be seen what means to the end their servants, the Commissioners, are going to take.

Dr. Philip Titus Heartt died at Waterford, N. Y., August 8, 1887. Dr. Heartt was born in Middlebury, Vt., in 1811, attended lectures at the University of Pennsylvania, passed his examinations with high honors, and was licensed to practise medicine by the Board of Censors of Albany County in 1832. He settled first in Troy, but having had several pulmonary hemorrhages, he was forced to relinquish the bright prospects that were opening before him in that city and seek the more healthful country. He then settled in Melrose, where he built up a large practice. Subsequently he removed to Waterford, where he succeeded to the practice of Dr. Porter. Dr. Heartt's eminent ability and sagacious counsels were unquestioned to the last, and though for the past five years he was compelled, by failing health, to abandon the active pursuits of his profession, he never refused the aid of his counsel to those who had been accustomed to rely upon it. In general literature and in the knowledge of men and books the doctor was accomplished, and he was, on this account, as well as by reason of his sterling character, a most agreeable companion. In conversation he was always pure of speech and decorous.

News of the Week.

International Medical Congress—Section on Diseases of Children.—The following papers are announced to be read in this Section: *Monday, September 5th:* 1. An Investigation to Determine whether the Absence of Sewage and of Water Pollution Diminishes the Prevalence and Severity of Diphtheria, by Dr. C. W. Earle, Chicago; 2. Rate of Growth in American and British Children, and its Bearing on the Investigation of Disease, by Professor W. Stephenson, Aberdeen, Scotland; 3. The Diseases of Faulty Habit, by Dr. J. F. Goodhart, London, England; 4. Deleterious Results in Children of a Narrow Prepuce and Preputial Adhesions, by Professor Lewis A. Sayre, New York. *Tuesday, Morning Session:* 1. The Milk Supply of the Cities, by Dr. Cyrus Edson, New York; 2. The Nutrition of Infants, by Professor Albert Leeds, Hoboken; 3. The Use of Cows' Milk in the Feeding of Infants, by Professor W. C. Vaughan, Ann Arbor. *Afternoon Session:* 1. Anatomical Characters of Membranous Croup, as Observed in Fatal Cases in the New York Foundling Asylum, by Dr. W. P. Northrup; 2. Remarks on Tubage of the Glottis, and the Manner in which it was Practised in France, by Dr. E. Bouchut, Paris; 3. Intubation of the Larynx, by Drs. Joseph O'Dwyer and Dillon Brown, New York; 4. Intubation *versus* Tracheotomy in the Treatment of Croup, by Professor F. E. Waxham, Chicago. *Wednesday, Morning Session:* 1 The Treatment of Strumous Glandular Enlargements of the Neck, by Dr. Martin Oxley, Liverpool; 2. Infantile Convulsions in Connection with After-Neurotic Tendencies, by Dr. J. A. Coutts, London; 3. A Study of Some of the Bacteria Found in the Dejecta of Infants Affected with Summer Diarrhœa, by Dr. W. D. Booker, Baltimore. *Afternoon Session:* 1. Hallucination in Young Children, by Dr. E. Bouchut, Paris; 2. Cerebral Irritation in Children, by Dr. Jules Simon, Paris; 3. Treatment of Diphtheria by Antiseptic Sprays, by Dr. Grancher, Paris; 4. Treatment of Physiological Derangements in Children Due to Overfeeding, by Dr. Cadet de Gassicourt, Paris; 5. Notes on the Malaria of Children in Brazil, by Dr. Moncorvo, Rio de Janeiro. *Thursday, Morning Session:* 1. Observations Regarding True Pneumonia in Children, by Professor A. D'Espine, Geneva; 2. Paper (title not announced), by Dr. Oscar Wyss, Zürich; 3. Some Observations on Headaches in Children and their Relation to Mental Training, by Dr. W. H. Day, London; 4. Scarlatinal Nephritis from a Clinical and Pathological Standpoint, by Dr. H. Ashby, Manchester; 5. On the Anatomical Characters of Scarlatinal Nephritis, by Dr. Frank Grauer. *Afternoon Session:* 1. The Contagious Principle of Pertussis, by Professor Alfred Vogel, Munich; 2. The Nature of Whooping-Cough and its Antiseptic Treatment, by Dr. Moncorvo, Rio de Janeiro; 3. Acetonuria in Children, by Dr. A. Baginsky, Berlin; 4. Hereditary Syphilis and Rachitis in Brazil, by Dr. Moncorvo, Rio de Janeiro; 5. Marasmus, by Dr. I. N. Love, St. Louis. *Friday, Morning Session:* 1. The Treatment of Lateral Curvature, by Dr. James Knight, New York; 2. Anchylosis of the Knee-Joint in a Straight Position by Excision as a Remedy for the Atrophy and Deformity following

Acute Poliomyelitis of Childhood, by Dr. Stephen Smith, New York; 3. Hip-Disease, Practical Points in its Treatment, by Dr. A. J. Steele, St. Louis. *Afternoon Session:* 1. Forcible Correction of Contracted Knee-Joint, by Dr. E. H. Bradford, Boston; 2. Progress of Orthopædic Surgery, by Dr. Noble Smith, London; 3. Section of Contractured Tissues Essential before Mechanical Treatment can be Effectual, by Professor L. A. Sayre, New York; 4. The Scope and Limitations of Orthopædy, by Dr. C. F. Taylor, New York; 5. The Principles of Treatment of Club-foot, Partly Demonstrated by the Exhibition of Apparatus, by Dr. W. E. Balkwell, London.

Pharmacists Insure Themselves.—The Wisconsin State Pharmaceutical Association, at its meeting in Milwaukee on August 10th, decided to organize a mutual fire insurance company, to escape what they considered extortion on the part of the regular companies.

A Charitable New Yorker.—An account is published in *The Hospital* of a picnic given to the convalescent patients of the Torbay Hospital (England). This picnic and several drives were paid for out of a "thank-offering" given by a gentleman from New York, who was so unostentatious in his charity that even his name was unknown to the hospital authorities.

A Legacy for the Berlin Medical Society.—A Portuguese physician, Dr. Pedro da Costa Alvasenda, died some years ago in Lisbon. He was childless, and left a large share of his fortune to various scientific institutions. The Berlin Medical Society was one of the legatees, and has just received from the estate 3,489,500 reis, about fifteen thousand dollars.

Death of Dr. N. A. Randolph.—A sad accident occurred at Atlantic City on Sunday, August 21st. Dr. N. A. Randolph, of Philadelphia, one of the editors of the *Medical and Surgical Reporter*, was bathing in the surf with his wife, when he was carried off his feet by the undertow, and disappeared beneath the waves. It is believed that heart-failure, rather than drowning, was the cause of his death. His wife was also nearly drowned, being brought to land in an unconscious condition by one of the bathers. Dr. Randolph was Professor of Physiology at the University of Pennsylvania, and was well known among the physicians of Philadelphia as a hard worker and thinker. He was but thirty-eight years of age.

The Doctors and the Jubilee.—The members of the medical profession in Great Britain do no think as much of the Queen's jubilee as they did some months ago. It was hoped that at least some one or more would be raised to the peerage, but this august estate still remains closed to them. Knighthood was offered to some, and accepted by a few in Great Britain, but the Irish were left out in the cold entirely, and never a title did one of them get, despite the fact that the British Medical Association met in Dublin.

No Room for Women.—The Omaha *World* reports that the medical college of that city refuses to matriculate women, and it says that by this action the college shows itself to be far behind the times.

The Cooper Hospital, built by the family whose name it bears, was opened a few weeks ago in Camden, N. J.

The Registration of Births.—The Board of Health has determined to enforce the law relating to the registration of births in this city, and threatens to prosecute all physicians who fail to report births. Clergymen who do not respect the law relating to the registration of marriages will also be proceeded against. It is said that the number of reported births has suddenly increased more than one hundred a week since the contemplated action of the Health Board was made public.

The Cholera is reported to be on the decrease in Sicily, but to be increasing in Malta and in certain parts of Russia.

The Red Cross.—The next international conference of the Red Cross Society will be held at Carlsruhe on September 19th.

The Medical Society of Virginia.—The eighteenth annual meeting of the Virginia State Medical Society will be held in Richmond, beginning on Tuesday, October 18th. The subject for general discussion is the "Choice of Anæsthetics," and the discussion will be opened by Dr. Hunter McGuire, of Richmond.

Dr. Graily Hewitt has been appointed Emeritus Professor of Obstetric Medicine in University College and Consulting Obstetric Physician to the Hospital.

Mad Dogs and Hydrophobia.—In the Department of the Loire, France, during 1886, 53 persons were bitten by mad dogs. Of this number 1 only died of rabies. Twenty-six were treated under Pasteur's directions, and the rest either received no treatment at all or were cared for by quacks. It was among the latter number that the death occurred.

The Injurious Effects of Blisters.—Dr. Wyss, of Geneva, is a strong opponent of the employment of blisters, which he considers an unnecessary cruelty to the patient, and an injury in that they prevent sleep, disturb the function of urinary secretion, and often give occasion to obstinate cutaneous eruptions. This same stand was taken by Dr. Goldmann, now of Galveston, in a letter to The Medical Record from Monterey, Mexico, in January, 1884. In this letter the author gave his reasons for his objections to blistering, and stated his belief that all the good effects of vesication could be obtained by other means which do not possess its drawbacks.

A Case of Quadruplets is reported by Dr. Lowry in Daniels' *Texas Medical Journal*. The children, all girls, were born prematurely at the sixth month. They all showed some signs of life, and one lived some minutes and cried faintly. Each child was enclosed in separate membranes with separate cord and placenta. The mother was a German woman, thirty-five years of age, married about a year to her second husband.

Tests for Color-blindness among Railroad Men.—The employees of the Reading Railroad complain that the color-tests have not been fairly conducted, and threaten to strike if they are tested on colors other than red, white, blue, and green, on boards, flags, and lamps.

Reviews and Notices of Books.

Elements of Botany. By Edson S. Bastin, A.M., F.R.M.S., Professor of Botany, Chicago College of Pharmacy, etc. 8vo, pp. 282. Chicago: G. P. Engelhard & Co. 1887.

The object of the author is stated in the preface to be to produce "a work which is not so technical but that any student of fair intelligence may take it up and pursue it without the aid of a teacher, and obtain a good foundation of the facts and principles of the science." He begs the student to recollect that botany is primarily the study of plants, and not the study of books about plants, and advises that all study be done *plant in hand*. Acting on this plan, he has been very successful in constructing a guide to the study of botany. The various parts treat of organography and vegetable histology, physiology and taxonomy. Gray's Manual is needed, in addition, for the actual analysis of the flora of the student's neighborhood. The cuts are well executed, the pages neat, and the style concise.

Treatment by Massage and Exercise. By Joseph Schreiber, M.D. Translated by Walter Mendelson, M.D., New York. 8vo, pp. 285. Philadelphia: Lea Brothers & Co. 1887.

Dr. Schreiber was formerly docent in the University of Vienna, and is now proprietor of a sanitarium in Styria, Austria. Since he began its preparation, the works of Busch, Reibmeyer, Samuely, and Rossbach have appeared in German, but the author claims to have presented the subject from a somewhat different point of view from many of the above authors. He commences with the history of mechano-therapy and its developments in the various countries of Europe. Then follow chapters on the description of massage, with a scientific explanation of its physiological effects. The various modes of mechanical interference are dealt with in detail, and the effects of gymnastic exercise on the various functions carefully noted. Finally, he enumerates the diseases amenable to mechano-therapy, with records of cases treated. The latter include sciatica-cervico-brachialgia, various neuralgiæ, and, in fact, about half of all the ills flesh is heir to. Diabetes and tonsillitis both find a place. An extensive bibliography is appended. The work of the translator has been admirably done.

A Practical Treatise on Renal Diseases and Urinary Analysis. By William Henry Porter, M.D., Professor of Clinical Medicine and Pathology in the New York Post-Graduate Medical School and Hospital, etc. 8vo, pp. 349. New York: William Wood & Co. 1887.

Dr. Porter's book will be read with interest, even though his conclusions may not be accepted in detail. He has clearly stated his deductions from ten years' study upon the various kidney-lesions in men and animals from both a clinical and pathological standpoint. He first gives elaborate descriptions of the anatomy and physiology of the kidneys, and then enters upon the detailed consideration of the diseases themselves. These latter are respectively acute and chronic parenchymatous metamorphosis of the kidney (under the latter head the kidney of pregnancy and the infiltrated kidney in wasting diseases); acute diffuse nephritis, the various forms of chronic diffuse nephritis; acute and chronic sclerosis; gouty kidney; hyaline, albuminoid, or waxy kidney. Then follow chapters on renal hemorrhage, hæmoglobinuria, anæmia, pyelo-nephritis, calculi, tuberculosis, tumors, parasites, diabetes, etc.

We have given this full table of contents (omitting some headings, however) because we really think that the author has produced a volume which can be read with great profit. It is in the chapters on parenchymatous metamorphosis that the most interest will be felt. Dr. Porter has before expressed his views on this subject, confining the term "inflammation" to its strict signification. He finds it difficult to see what relation the change called "parenchymatous metamorphosis" bears to "inflammation." Accordingly, the term "parenchymatous nephritis" is not accepted. "In treating this lesion," he says, ". . . it should be remembered that it is not of an inflammatory nature, but that it results from too much work being thrown upon the kidneys, which undergo this metamorphosis through their efforts to relieve the system."

Another suggestive observation is made concerning renal complications following surgical operations. "In all major surgical operations, but especially those in connection with abdominal surgery, there is a strong tendency to the development of an acute parenchymatous metamorphosis of the kidneys. The evidence of this lesion usually appears on the second or third day after the operation, when the quantity of water decreases, the color deepens, the specific gravity increases, and albumin and casts become more or less abundant." The causes of this condition are referable to the initiation of the anæsthetic and the shock of the operation, the increase in the amount of the effete material as a natural sequence to the increased nutritive activity necessary for the reparative process, and, finally, the use of opium, so often necessary, which closes up the alimentary and respiratory emunctions and forces more work upon the kidneys. In the operation of these causes he finds reason for the "septic symptoms" which supervene upon an operation where the urine may have been normal. He recommends in these cases copious draughts of simple or medicated water, which will relieve very speedily the threatening renal symptoms.

The second part of the volume is devoted to urinary analysis, and is unusually complete. The author pays special attention to the physiological indications, with their bearings on clinical medicine. This is a point on which works of this kind are apt to be sadly deficient. The drawings of the various urinary deposits are exceptionally fine.

Dr. Porter is certainly to be congratulated upon the general make-up of this volume. Non-assent with some of its conclusions will in nowise diminish the pleasure of its perusal.

Ninth Biennial Report of the State Board of Health of California, for 1886. By G. G. Tyrrell, M.D., Secretary of the Board.

The efficient Secretary is to be congratulated on having compiled so readable a volume. Full reports are given of the topography, botany, and climatology of the various regions of the State.

The mortality reports from the various districts are unusually full and accurate.

Medical and Surgical Memoirs. By Joseph Jones, M.D., Professor of Clinical Medicine, University of Louisiana; Visiting Physician, New Orleans Charity Hospital, etc. 8vo. Vol. I. Pp. 820. 1876. Vol. II. Pp. 1348. 1887. New Orleans.

These large volumes record the various experiences of the author, scattered over a busy life. He has been at work for over thirty years on the chemical and microscopical changes occurring in the blood in malarial fever. Many of the observations noted were made during Dr. Jones' service in the medical corps of the Confederate armies. The vastness of the ground covered forbids an extended review. One interesting case noted is that of the murder of a man named Narcisse Arrieux. A man was arrested on suspicion. Stains on the latter's clothing were proved by Dr. Jones to be blood, and that, too, of a man suffering from malarial fever. The victim had suffered from this disease for some weeks before his death, and examination of blood-stains on his own clothes, made by the murder, revealed the same characteristics as those on the clothing of the

suspected person. On this evidence the jury brought in a verdict of guilty. Dr. Jones claims that this is the first case of its kind on record.

Dose and Price Labels. By C. L. Logeman. Philadelphia: Dunlap & Clarke. 1887.

This is primarily intended for pharmacists and physicians who keep large stocks of medicines on hand. The printing is neatly done, and all the labels for poisonous preparations are distinguished by heavy black lines.

Earth as a Topical Application in Surgery. By Addinell Hewson, M.D. 12mo, pp. 309. Philadelphia: The Medical Register Company. 1887.

This is the second edition of Dr. Hewson's book, the first having been issued several years ago. The first portion is occupied with the history of over ninety surgical cases in which earth was used as an antiseptic dressing. Then follow comments thereon, and a chapter on the mode of action of this therapeutic agent. The ideas expressed, though novel at the time of their first presentation, are now generally accepted by surgeons. The use of peat is, however, more common than that of "earth" proper, by which Dr. Hewson refers to "yellow subsoil, common everywhere in our city (Philadelphia), well dried and sifted through a fine flour-sieve, rich in ferruginous clay, and entirely free from all sand, grit, or foreign matter." The author regards earth as a deodorizing sedative, and with distinct antagonism to putrefaction and inflammation. He considers that the nature of its action is a chemical one. His volume is a most readable one, though we may not accept all his conclusions.

Maternity, Infancy, and Childhood. By John M. Keating, M.D., Visiting Obstetrician, Blockley Hospital, etc., Philadelphia. 12mo, pp. 221. Philadelphia: J. B. Lippincott Co. 1887.

These papers have been compiled from the author's lectures to students and nurses. No especially new ideas are advanced, but common-sense shines through every page. Practical observations are made upon the various infant foods in the market. Dr. Charles S. Turnbull adds a valuable chapter on the care of the eye and ear. Dr. Alexander McCoy also contributes practical information. The book is a proper one to recommend to patients.

Cathartics and Emetics. By Henry M. Field, M.D., Professor of Therapeutics in Dartmouth Medical College. 12mo, pp. 288. Philadelphia: P. Blakiston, Son & Co. New York: J. H. Vail & Co. 1887.

This work must be regarded as a valuable addition to medical literature. Its contents are hardly found in any other English work, or, for that matter, in any familiar language. The author makes constant allusions to Fonssagrives, as "this writer's works have not been given directly to the English-reading public," and because "they are charged throughout with the most valuable suggestions and statements of rational theory and of fact."

In these latter days too little stress is laid upon catharsis and emesis as remedial measures. Our forefathers doubtless erred on the side of rigor in this respect, but we have gone to the other extreme. Dr. Field takes up in detail the various evacuant remedies, speaking of their materia medica, special actions and uses, inconveniences, contra-indications, and toxic action. Many valuable practical points concerning administration are scattered throughout the pages. Finally, there are inserted chapters on the mechanism of catharsis and emesis, with respective indications and contra-indications. To a young practitioner the perusal of this volume cannot fail to be of inestimable benefit. If we should venture to make a single criticism, it would be to condemn the too frequent allusion to the special preparations of one firm of manufacturing druggists.

A Companion to the United States Pharmacopœia (last edition). By Oscar Oldberg, Ph.D., and Otto A. Wall, M.D., Ph.G. Second revised edition. 8vo, pp. 1216. New York: William Wood & Co. 1887.

This is primarily a work for pharmacists, and is designed as "a ready-reference book and a working manual." It contains descriptions of all remedies and preparations in use in the United States, whether officinal or not. Included is a brief statement of medicinal uses and dosage. It is an invaluable work of reference. The almost complete neglect of such works by physicians has been frequently deplored. No better volume than this for supplying the needed information has appeared. The fact that this is its second edition attests its worth and the appreciation in which it is held. Two authors better qualified for such a task could not be found.

The Separate System of Sewerage: its Theory and Construction. By Cady Staley, President Case School Applied Science, Cleveland, and George S. Pierson, C.E. 8vo, pp. 183. New York: D. Van Nostrand. 1886.

This is a manual for all interested in sanitary science. It describes in full the principles and appliances of the "separate" system so clearly that anyone of ordinary intelligence can understand the workings of this method of sewerage. Special attention is paid to sewer-ventilation. Full descriptions are given of the various kinds of pipes, man-holes, flush-tanks, etc.

Analysis of the Urine: With Special Reference to the Diseases of the Genito-Urinary Organs. By K. B. Hofmann and R. Ultzmann. Translated by T. Barton Bruni, A.M., M.D., and H. Holbrook Curtis, Ph.B., M.D. Second edition, revised and enlarged. 8vo, pp. 310, with eight lithographic plates. New York: D. Appleton & Co. 1887.

That this work is a valuable and practical one is attested by its continued popularity. It is not a mere compilation of the work of others, but contains the result of years of careful research. It gives many details that will be found most helpful to students of urinary analysis as well as to general practitioners. The lithographic plates at the end are very accurate. The book ranks among the best of its kind, and we can heartily commend it.

Sphygmography and Cardiography, Physiological and Clinical. By Alonzo T. Keyt, M.D. Edited by Asa B. Isham, M.D., and M. H Keyt, M.D. New York and London: G. P. Putnam's Sons. 1887.

The medical profession of America is to be congratulated on the appearance of this work of the late Dr. Keyt. For it comprises a collection of the many contributions of the author to sphygmography and cardiography—contributions which were conducted with intelligence, conscientiousness, and skill, and which entitle the author to a distinctive place among American physicians who have made original research. Dr. Keyt, we are told, pursued unremittingly his studies of his graphic method, and in this labor was insensible alike to the suggestions of hunger and fatigue. He added much to the extent and definiteness of our knowledge of the physiology and pathology of the circulatory apparatus, and there can be no complete or intelligent account of sphygmography ever written which will not have to employ some of the results of his labors.

The papers in the present volume cover the subject of the history of the sphygmograph, with chapters on the form of the sphygmogram and cardiogram, and on the pulse-wave velocity. There are also ten clinical chapters, dealing with the sphygmography and cardiography of cardiac and aneurismal disease. The book is copiously illustrated.

Physiological Laboratory, Harvard Medical School. Boston. Collected Papers II., 1880–1886. For private circulation.

The volume before us contains many valuable papers. Those on phthysmographic work, the laryngeal muscles, illusions of motion, and on sense of sight and touch, will perhaps attract most attention.

Medical Electricity. A Practical Treatise on the Applications of Electricity to Medicine and Surgery. By Roberts Bartholow, A.M., M.D., LL.D. Third edition, enlarged and improved. With one hundred and ten illustrations. Philadelphia: Lea Brothers & Co.

Dr. Bartholow writes excellent books, and this is not an exception. It is a brief and, on the whole, a lucid description of electro-therapeutics, electro-physiology, and electro-physics. We can only suggest in criticism that his electro-physics is decidedly crude and behind the technical knowledge of the day. Like most writers on this subject, he overestimates the value of his agent, or at least gives that impression. His statements of the physiological effects of static electricity, as given on page 154, are most misleading, not to say inaccurate. These few imperfections do not, however, impair the general high character of the work.

A Treatise on Simple and Compound Ophthalmic Lenses, their Refraction and Dioptric Formulæ, including Tables of Crossed Cylinders and their Sphero-Cylindrical Equivalents. By Charles F. Prentice. Pp. 42. New York: James Prentice & Son.

This is a valuable technical work for opticians and oculists.

Spasm in Chronic Nerve Disease; being the Gulstonian Lectures for 1886. By Seymour J. Sharkey, M.A. and M.B. Oxon, F.R.C.P. London: J. & A. Churchill. 1886.

These lectures have already received extended notice in various journals. They discuss the subject of spasm due to intra-cranial and spinal disease, and functional spasms. The author gives his views of the pathology of spasm, and also much that is interesting in the way of anatomical description and illustrative clinical cases.

Klinik der Verdauungskrankheiten. Von Dr. C. A. Ewald. I. Die Lehre von der Verdauung. Zweite neu bearbeitete Auflage. Berlin: Verlag von August Hirschwald. 1886.—The Disorders of Digestion. By Dr. C. A. Ewald. I. The Physiology of Digestion.

The first edition of Professor Ewald's work has been translated into English, and was at once recognized as a masterly exposition of this branch of physiology. The present edition contains the changes made necessary by the recent rapid advances in gastric physiology. We know of no work extant which gives a better or clearer presentation of the subject with which it deals.

Anæmia. By Frederick P. Henry, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. Reprinted from *The Polyclinic*. Philadelphia: P. Blakiston, Son & Co. 1887.

This is a well-written monograph, which is interesting chiefly in its conservative adoption of the more modern views regarding the essential nature of anæmia. The writer sensibly prefers the old word, anæmia. The functional power of the blood is the basis of his argument, and he believes in the superiority of the hæmoglobin-test over the numerical standard of the red blood-corpuscles. In other words, the red corpuscle is not a constant quantity, but the amount of hæmoglobin in two from different persons may vary as much as fifty per cent., so that "the number of corpuscles does not afford an infallible proof of the presence or absence of anæmia." "As a rule, however, when the number of red corpuscles is normal, the amount of hæmoglobin is also normal, or nearly so, but there are numerous exceptions to this rule."

His classification includes (1) primary, (2) secondary, (3) toxanæmias, and (4) parasitic anæmias. He speaks of chlorosis as the anæmia of puberty, but the term chlorosis is too convenient to be readily abandoned.

La Thérapeutique Médico-chirurgicale en 1886. Revue des travaux français et étrangers. Publiée sous la direction du Dr. Paul Rodet. Pp. 418. Paris: Librairie, J. B. Baillière. 1887.

Dr. Rodet's annual review of therapeutical progress seems to be very complete, and as it covers the practical side of medical work, it ought to be popular.

Practitioner's Handbook of Diseases of the Ear and Naso-pharynx (third edition of the "Aural Surgery"). By H. Macnaughton Jones, M.D., M.Ch., M.A. Oxon (Hon.). London: J. & A. Churchill. 1887.

The author states that the present work is practically a new book. It is systematic in arrangement, clear and, for the most part, concise in statement. The articles on the naso-pharynx are chiefly contributed by Dr. Morell Mackenzie. The colored plates form an interesting and instructive feature of the work. On the whole, we believe that Dr. Jones' work will prove to be a useful handbook to the practitioner.

Hystérie et Traumatisme: Paralysies, Contractures, Arthralgies, Hystéro-traumatiques. Par le Dr. Paul Berbez. Paris: Aux Bureaux du *Progrès Médical;* A. Delahaye et Lecrosnier, Éditeurs. 1887.

This work has an especial interest in its connection with railroad injuries, for the author shows that, indubitably, traumatisms may cause hysterical phenomena of the most pronounced character. The author has done good service, therefore, in collecting facts bearing on this subject. His historical introduction is incomplete. He even makes no mention of Erichsen's work.

Sur un Nouveau Traitement de la Métrite Chronique, et en particulier de l'Endométrite par la Galvano-caustique chimique intra-utérine. Par le Dr. G. Apostoli. Paris: Octave Dion. 1887.

This book contains an account of Dr. Apostoli's method of treating chronic uterine inflammation by the galvano-cautery.

Manuel pratique de la Garde-malade et de l'Infirmière. Publié par le Dr. Bourneville. Tome I. Anatomie et Physiologie. Tome II. Pansements. Tome III. Femmes en Couches.—Médicaments. Petit Dictionnaire. 3e edition, revue et augmentée. Paris: Aux Bureaux du *Progrès Médical.* 1887.

Dr. Bourneville's work is one written by a number of collaborators, and necessarily varies a little in the value of its contents. Rather too much space proportionately is given to surgical nursing. The book is, on the whole, a fairly good manual for trained nurses, a class of works much in demand at the present time.

A System of Practical Medicine, by American Authors. Edited by William Pepper, M.D., LL.D. Assisted by Louis Starr, M.D. Volume V. Diseases of the Nervous System. Philadelphia: Lea Brothers & Co. 1886.

Pepper's system concludes with the present very large and interesting volume, in which one can find further evidences of thorough and careful work. Dr. Seguin opens with a chapter on general symptomatology and diagnosis, and one on the localization of lesions in the nervous system. In the latter chapter the diagrams of the spinal cord are hardly complete, not showing the anterior ascending columns, the columns of Lissauer, or

indicating the probable central position of the vaso-motor and secretory fibres. The columns of Clark, also, one would suppose, should be found in the cervical enlargement. The cuts illustrating cranio-cerebral topography might now be amplified so as to show other than motor centres. At the time the chapter was written, however, the author would perhaps have hardly been safe in going into more detail than he does.

The chapter on mental diseases, by Dr. Folsom, is a good presentation of the subject of insanity, and one which the practitioner can read with both interest and profit. We can only speak with praise of the articles by Dr. Mills on hysteria, hystero-epilepsy, and catalepsy. An almost undue amount of space is given to hystero-epilepsy, which, in its typical form, seems mostly confined to La Salpétrière.

Dr. Sinkler's article on athetosis is practical, but not so complete in its study of the pathology as could be wished. The placing of Thomsen's disease, along with eclampsia, among local convulsive disorders is, to say the least, a curious arrangement.

The chapter on epilepsy, by Dr. Hamilton, is hardly up to the reputation of its author. One of the most valuable pieces of work in this book is that on the "Neural Disorders of Writers and Artisans," by Dr. Morris J. Lewis. This embraces some very important original work on the subject of telegraphers' cramp. Dr. Lewis has done well, also, in drawing attention to the subject of professional muscular atrophy.

Dr. Wilson's articles on alcoholism, the opium-habit, and chronic lead-poisoning, furnish the reader with the latest views upon these topics. We may except, perhaps, his paragraph upon the morbid anatomy of plumbism, since recent investigation has shown beyond doubt that lead does produce disease of the nerves, as well as at times of the spinal gray matter.

Dr. Spitzka, in his articles on cerebral hyperæmia and anæmia, treats a difficult subject with skill and good judgment. His descriptions of the chronic inflammatory and degenerative affections of the spinal cord show a thorough mastery of the subject, but lack somewhat in perspicacity and a systematic evolution of some of the subjects discussed.

One of the valuable features of the present work is that it treats of a number of the rarer nervous disorders, such as narcolepsy, myxœdema, erythromelalgia, etc. The various articles are illustrated, though not profusely.

The volume, as a whole, forms a contribution to neurology of which American medicine can be proud.

Two Comedies: An Ill Wind; An Abject Apology. By F. Donaldson, Jr. Boston: Cupples, Upham & Co. 1887.

Medicine and Medicine-men. Anniversary Address, delivered at the banquet of the Louisville Medical Society, May 26, 1887. By John Godfrey, Surgeon, M.H.S. Louisville, Ky.: John P. Morton & Co. 1887.

Dr. Godfrey's poem shows some humor and metrical ingenuity. Dr. Donaldson's comedies have a good deal of cleverness about them, and show decidedly the possession of literary talent. They both make interesting reading, despite some conventionality of sentiments and a rather excessive use of quotations. The book is daintily printed and bound.

The Climatic Treatment of Consumption: A Contribution to Medical Climatology. By James Alexander Lindsay, M.A., M.D. 8vo, pp. 228. London and New York: Macmillan & Co. 1887.

The present interest in climatology makes the work before us a very timely one. Dr. Lindsay is fully equipped, by a most extensive personal experience, for writing about the different health-resorts. He has visited Australia, California, Algeria, and nearly all the chief resorts in Europe. This, combined with a practical experience as physician to the Consumptive Hospital near Belfast, and other institutions, ought certainly to give value to his opinions. He begins his book with a chapter on the causes of consumption, and follows this with chapters on the general principles of climatic treatment. The various health-resorts are then described in detail. American readers will be disappointed in finding no reference to Colorado, perhaps the best climate for consumptives in the world; or to Florida, which deserves the reputation it has got. The book is written also mainly from the standpoint of the consumptive, very little being said definitely regarding suitable climates for the rheumatic, nervous, etc. Still, we can heartily commend the book both to physicians and the laity. It will be a help to all who contemplate a voyage for health.

The Vest-pocket Anatomist. By C. Henri Leonard, A.M., M.D. Thirteenth revised edition. Detroit: Illustrated Medical Journal Co.

The worst we can say about this popular work is that it is founded upon Gray. We wish it were founded upon a treatise of better standing in the eyes of good anatomists and teachers.

Wear and Tear; or, Hints for the Overworked. By S. Weir Mitchell, M.D., LL.D. Harv. Fifth edition, thoroughly revised. Philadelphia: J. B. Lippincott Co. 1887.

It is not necessary to commend this most interesting and already widely known brochure. We shall only venture the criticism that Dr. Mitchell's views of making girls study only three or four hours until they are seventeen years old are most pernicious and liable to mislead. Girls are not made to study enough as it is. The present methods are wrong enough, but the trouble is not excessive quantity—it is poor educational methods.

L'Année Médicale (Neuvième année) 1886. Résumé des progrès réalisés dans les sciences médicales. Publié sous la direction du Dr. Bourneville. 8vo, pp. 402. Paris: E. Plon, Nourrit & Cie. 1887.

This is one of the best of the annual reviews of medical progress.

Sketches and Impressions, Musical, Theatrical, and Social (1799–1885), Including a Sketch of the Philharmonic Society of New York. From the after-dinner talk of Thomas Goodwin, Music Librarian. By R. Osgood Mason, A.M., M.D. Pp. 294. New York and London: G. P. Putnam's Sons. 1887.

Dr. Mason has made an entertaining volume, and one that will be especially appreciated by old New Yorkers. The reminiscences are mainly musical and theatrical, and the book is entirely from the "shop." The typography and press work are admirable.

Bibliothèque Diabolique (Collection Bourneville). Sœur Jeanne des Anges, Supérieure des Ursulines de Loudun (XVII^e Siècle). Autobiographie d'une hystérique possédée, d'après le manuscrit inédit de la Bibliothèque de Tours. Annoté et Publié par les Docteurs Gabriel Legué et Gilles de la Tourette. Préface de M. le Professeur Charcot. Pp. 321. A. Delahaye & Lecrosnier, G. Charpentier & Cie., Éditeurs. Paris: Aux Bureaux du *Progrès Médical*. 1886.

This work consists mainly of the autobiography of a nun who believed herself possessed and described her sensations with graphicness of detail. A study of her story shows now that she was a hystero-epileptic and must have passed through all the phases that have of late been so carefully described by Charcot and his pupils. Her work is, therefore, a contribution to hysteria in history, and also to psychology, for her confessions bear comparison with those of St. Theresa.

OXYGEN IN THERAPEUTICS. A Treatise explaining the Apparatus, the Material, and the Processes used in the Preparation of Oxygen and other Gases with which it may be Combined; also, Its Administration and Effects, Illustrated by Clinical Experience of the Author and Others. By C. E. EHINGER, M.D. 8vo, pp. 157. Chicago: W. A. Chatterton & Co.

By the enterprise of quacks, oxygen and compound oxygen have been long prominently before the public. Considerable scientific work has also been done in testing the therapeutic value of oxygen-gas. Dr. Ehinger has put together many of the facts recorded and added the results of his own experience. His book is really a useful contribution, therefore. We do not rate oxygen very high as a remedial agent, but it certainly has value, and possibly more than it is as yet believed by most physicians to possess.

THE CURABILITY OF INSANITY AND THE INDIVIDUALIZED TREATMENT OF THE INSANE. By JOHN S. BUTLER, M.D. New York and London: G. P. Putnam's Sons. 1887.

THIS is an interesting little brochure advocating the need of individualized treatment for the insane.

ELEMENTARY MICROSCOPICAL TECHNOLOGY. A Manual for Students of Microscopy. In Three Parts. Part I. The Technical History of a Slide, from the Crude Materials to the Finished Mount. By FRANK L. JAMES, Ph.D., M.D. Pp. 107. St. Louis, Mo.: St. Louis Medical and Surgical Journal Co. 1887.

WE should expect a thorough, intelligent, and practical treatise from Dr. James, and that is just what the present work promises to be. The details are carefully given; the illustrations and typographical appearance are superior.

SERIES OF PRACTICAL LESSONS IN NURSING. OUTLINES FOR THE MANAGEMENT OF DIET, OR THE REGULATION OF FOOD TO THE REQUIREMENTS OF HEALTH AND THE TREATMENT OF DISEASE. By EDWARD TUNIS BRUEN. Pp. 138. Philadelphia: J. B. Lippincott Co.

THE present work covers, in a very condensed way, nearly all the subject of diet, from the physiology of digestion to the special dietetics. The principles laid down are correct, and we can find no fault with the author except that he has not had the space to give more details. On the debatable questions of diet in gout and rheumatism the author is both judicious and cautious, and one will correctly infer that there is no specific diet or hard and fast rule for those diseases.

PHYSOSTIGMINE IN CHOREA.—Riess has recently warmly recommended hypodermic injections of physostigmine in chorea, and claims that the duration of the disease is thereby shortened to only fifteen days on an average, reckoning from the beginning of treatment. In a few cases the choreic symptoms ceased in five or six days. One-sixty-fourth of a grain of eserine sulphate was injected twice a day, and a strengthening treatment generally was adopted. The injections were found useless in very severe forms of chorea with a fatal tendency, also in cases of habitual chorea in adults. Among Riess' forty cases four belonged to the very severe forms: the rest were cured by physostigmine. This success induced Riess to try the influence of this drug in other hyperkineses, and partial success was obtained in tetanus, tremors, paralysis agitans, multiple sclerosis of brain and spinal cord, Charcot's post-hemiplegic chorea, and, finally, in one case of hysteria in the male with extreme emotional excitability and remarkable increase of all reflex movements. The preparation used was supplied by Merck, of Darmstadt.

Reports of Societies.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION IN DUBLIN.

(SPECIAL REPORT FOR THE MEDICAL RECORD.)

ADDRESS IN SURGERY.

ON Thursday Aug. 4th, Professor Edward Hamilton delivered his address in Surgery. A large part of the address was devoted to the discussion on antisepticism and its value. No honest or impartial observer, he said, could fail to recognize the deep debt of gratitude we owed to the Listerian system. It might be wrong in practice, and founded on an erroneous theory, but wonderful results had followed its introduction. Yet, with this triumphant record, we now found some of its most devoted adherents relaxing its stringency, and abandoning parts of the system which were long regarded as essential, and that, too, without any diminution of successful results. It was proved that the atmosphere was infested with myriads of minute organisms possessed of vitality. These organisms were subject to constant changes, and these changes were largely influenced by the surroundings among which the organisms were situated. In their turn, also, the organisms reciprocated and produced disturbance in the material surrounding them. It had also been established beyond controversy that some of these organisms were incapable of development or growth in the tissue or fluids of the living body, and could only undergo their life-changes when surrounded by material which was dead and, therefore, amenable to the physico-chemical laws. Others, again, were capable of maintaining their independent vitality in living tissues, where they increased and multiplied, disarranging the whole organism into which they had found their way. In the first variety the effect produced was in direct proportion to the actual amount of the ferment introduced. In the second, the effect was out of all proportion to the minute quantity of the noxa producing it. These latter bodies were potent causes of suppuration and infective inflammation. Experiments had proved beyond doubt that injury might be inflicted on the deep tissues of the living body, either by mechanical, chemical, or physical noxa, and if due cleanliness of the instruments were observed, and air excluded, no effect whatever was produced beyond the injured spot. These observations proved conclusively that these aerial entities were capable of producing suppuration and infective inflammation, but it had not been established that they were the sole and only origin of such phenomenon. But the facts determined by Ogston, Kocher, and others, that they might enter the interstitial tissues through the respiratory or digestive tract, were gradually narrowing the ground uncovered by their influence, and explained away the apparent spontaneity of such diseases as ulcerative endocarditis and infective periostitis, where these atoms were found crowding the deepest organs without any wound or breach of surface to account for their entrance. It must, therefore, commend itself to the ordinary understanding that it was our duty to destroy and exclude these aerial bodies from the body with all the care we could. The difficulty was to find the most suitable germicide—one which would act efficiently without being poisonous to the tissues or to the system at large; carbolic acid, corrosive sublimate, iodoform, thymol, had each for a time enjoyed the crown for a few months, only in their turn to be deposed. It was even now proposed to attack one set of atoms by an opposing army of a different species of atoms, and thus effect their annihilation—thus reminding us of the couplet:

> Little fleas have other fleas and smaller fleas to bite 'em;
> These lesser fleas have smaller fleas, and so *ad infinitum*.

This warned us that there was another side of antisepticism which had been almost entirely neglected. It

would appear that up to the present the attention had been exclusively fixed on infective germs. Sufficient regard not being had to the important influence of environment, every effort had been strained to discover the most effective and deadly germicide. We knew, however, that these atoms, no matter how virulent they might be, could not undergo their life-changes, could not produce these infective results, unless the environment were capable of developing and sustaining these changes. Deposited on clean metal, glass, or porcelain, they died of inanition; they exercised no influence whatever, and were amenable to none. In contact with dead organic matter, or living matter in certain conditions of altered or reduced vitality, they became a teeming source of infection, decomposition, and decay. If pathological surfaces could be brought into such a condition that they would not afford a suitable cultivation-ground, did we not accomplish almost as much as when we destroyed them? As examples of the influence of environment, Professor Hamilton quoted the protection afforded by vaccination against the germ of small-pox, the protection of the blood by the previous action of exanthemata. The bacilli of splenic fever, so destructive to the herbivora, took little effect on carnivora, and none at all on the pachydermata. The bacilli which would cause septicæmia in the mouse were powerless against the field-mouse. Comparative pathology would enlarge our views of human pathology. The influence of environment on the ripening of fruit was mentioned, it being possible, said Dr. Hamilton, to hasten the ripening of fruit for prize competitions by interposing between the prize specimens fruit of the same species which were already ripe. The treatment of chronic abscess was then dwelt upon at some length. He himself employed a weak solution of chloride of zinc (1 in 200), and employed it as follows: A long curved trocar and cannula was pushed through the abscess and made to transfix it some four or five inches. A piece of rubber tubing (with a single hole in the centre) was then drawn through the opening. Through this tube the antiseptic solution was allowed to flow continuously at a slow rate. The contained fluid and the abscess-wall were thus rendered perfectly aseptic. After about a week the openings enlarged and were no longer water-tight. This had at first caused considerable trouble, but more extended experience proved that, after the first week, continuous irrigation was not necessary, but that an occasional syringing was quite sufficient for the healing of the cavity.

ADDRESS IN PUBLIC MEDICINE.

The address in Public Medicine was delivered by the Rev. Samuel Haughton, M.D., the Senior Fellow of Trinity College, and one of the few men who combine in themselves the functions of a clergyman and a doctor. To some persons this address is often looked upon as rather dull, but Dr. Haughton infused into it so much life, such great interest, and even amusement, that this year it was the most successful of all—the one *pièce de résistance* of the Dublin meeting.

Dr. Haughton is a great personality in Dublin. Those who only know him as the distinguished mathematician, like those who think of him as the representative of Trinity College and, it may be added, of Irish learning, would have been amazed, if they had been present, to hear him extract, from columns of statistics and abstruse calculations, reflections of such moral significance and gems of genuine Irish humor, evoking at one time the most hearty applause, at another the loudest laughter, of his audience. It is impossible to give a summary that will convey to the reader a taste of what was the life in his address, and when published, it will be found to have lost most of its significance in the absence of the author's delivery.

REFLECTIONS ON THE DEATH-RATE.

The title of Dr. Haughton's address was "Reflections on Death-rate, with Special Reference to Dublin and its Suburbs," and he started with the statement that every human being is born with these natural rights—liberty, air, water, food, heat, and light. The three most important are air, water, and food. Without air we can only live about three minutes; without water, about three days; without food, about three weeks. These we seek by instinct stronger than reason and claim by force, if needs be, but how slow has been our progress to recognize that all others have equal claims to them. For eighteen hundred years the Christian world accepted slavery, and even the aged Paul sent back a runaway slave, apparently unconscious of his equal rights to freedom. For one hundred and fifty years, ending 1851, a window-tax deprived millions of their fair share of sunlight and air, a tax as monstrous as that of Vespasian on urine. The supply of water to the poor has also been just as much restricted. In the last fifty years London has increased its supply five-fold, but the inhabitants have in the same period increased four-fold. At present the supply was described by the orator, from the point of view of an Irishman, as "good enough for Londoners," though not equal in quality to that of Dublin or Glasgow. But Ireland is not generally well off, and a water was named as once drunk when it contained as much ammonia as sewage.

The relation of the death-rate to density of population was then lucidly stated, with an apology for the necessary mathematical formulæ, which, though agreeable to the speaker, were, he well knew, hateful to a public assembly. Dr. Haughton explained Farr's formula, pointed out its error, and furnished the necessary correction. He then presented a table which he had prepared, showing the death-rate calculated from the densities, from which it is easy to see at once the proper average death-rate, and how far it deviates from that of health. He found that in certain sparsely populated districts, some million of country people had ten thousand less funerals to attend in a year, and then he described them as a dull race, who did not live but vegetated, ignorant of Greek, Latin, Shakespeare, Newton—and he ought to have added, mathematics. He would prefer, he said, to live among livelier people, and take his chance of a share among the ten thousand extra funeral feasts.

He then showed the effect of sanitary measures in London, Edinburgh, and Dublin, showing that in the two former these effects were four times as powerful as in Dublin, although the last had excellent water. As to Dublin and its suburbs, he summed up another table in the statement that, for every thousand persons living in the overcrowded liberties and slums of Dublin, five more must die each year than in the suburbs; and then solemnly warned the latter, in a quotation they dared not dispute, that "the voice of their brothers' blood cries from the ground." This, he said, is the old story—the saddened lives and early deaths of the poor cry continually from earth to heaven, and at times the silent cry is answered. Then, when pestilence leaves its congenial haunts and carries terror into the homes of the rich, increased offerings come to the hospitals; but they are of no more value than the large sums poured into the temple-treasury of Jerusalem, because they are but sacrificed to the fetich of pestilence, wrung from the rich by terror as abject as their former selfishness was mean.

As to the quarrel between city and suburb, Dr. Haughton ventured on three lines of Horace, and when some of his audience looked bewildered, and others thought it a good time to vent their applause, he interjected a condensed translation—both are in the wrong.

Another interesting table showed the relation of death-rate to absence of heat. From this it appeared that a fall of temperature from 40° to 32° F. means an increase in the death-rate of 5.6 for London, but of 8.9 for Dublin. The real cause of the high Dublin rate was attributed to the poverty of a large proportion of the inhabitants. It is, therefore, beyond the control of sanitary authorities.

It is always there, whatever the cause, and it calls for continual alms to relieve the suffering. The orator, who had enchained his audience throughout, closed with an effective appeal not to despair, but to bear in mind Peter's answer to the divine Lord, "Master, we have toiled all night and taken nothing; nevertheless, at thy word, I will let down the net."

SECTION OF SURGERY.

Wednesday, August 3d.

The President of the Section, Sir George Porter, delivered a few introductory remarks but said he would not give any formal address, as it would only take up the time and prevent papers from being read.

Mr. Mitchell Banks, of Liverpool, then opened a discussion

ON THE RADICAL CURE OF HERNIA.

He described his own method of operating and presented a table containing particulars of 106 cases, 68 of which were cases of non-strangulated hernia, 52 being moderate in size, and the remaining 16 very large and incapable of support by trusses; 38 were cases of strangulated hernia. Of the 52 herniæ of moderate size, 1 death was distinctly due to the operation. Of the 16 herniæ of very large size, 4 cases proved fatal—2 of these deaths being from septicæmia. Of the 38 cases of strangulated hernia, 3 proved fatal. Of the 90 cases of moderate-sized unstrangulated hernia and strangulated hernia combined, 24 died, or could not be traced, leaving 60 whose cases had been followed up; 44 of these were "quite sound." The rupture had not come down since the operation, there was nothing in the way of a lump to be felt or seen, and no impulse on coughing. Some patients wore trusses for the sake of protection, and some did not, but all were encouraged to do so. Seven cases were partially successful, in so far that, although there was distinct evidence of a hernia after the operation, a truss could be comfortably worn. He had operated on children in very few cases. He believed that there were very few cases in children that were not curable by a truss worn for a sufficiently long time. Mr. Mitchell Banks said there was a danger in a patient leaving off his truss after operation, as such a patient had a weak place in his inguinal canal.

Dr. Macewen (Glasgow) then spoke, and explained on a model the various steps of the operation he himself performed.

Dr. Keetley (London) then spoke of the treatment of hernia for radical cure by injection, and gave the subsequent history of a case he had detailed at the Cardiff meeting in 1885. Of his own cases, four patients (representing five herniæ) were cured. Three patients (representing four herniæ) derived no benefit so far as he could make out, but described themselves as better. He had only operated on one patient by subcutaneous injection, and failed. He had used for the injecting fluid first absolute alcohol and then glycerine of tannic acid. He believed failures were due (1) to not using enough fluid; (2) to the fluid not getting into the canal; and (3) to the fluid gravitating. The treatment by injection was somewhat uncertain in results, but it was eminently safe. But some cases of congenital hernia were unfit for any form of radical cure whatever. Referring to large umbilical herniæ, Mr. Keetley advised the wearing of a bandage for such cases. He pointed out that the fact of Mr. Banks having only operated on one case of umbilical hernia showed, either that surgeons must be very unwilling to operate on these cases, or else that the patients were very unwilling to be operated on, as such cases were to be met with by the dozen.

Dr. Ball (Dublin) spoke of the method of operating by performing torsion of the sac. The sac was first isolated as far as possible from the surrounding tissues—and this was often difficult, but it must be done thoroughly. A short pair of blunt-pointed scissors was very useful to separate it from the surrounding tissues. Having ascertained the sac to be empty (and if necessary opening it for the purpose), it was first twisted and then ligatured as high as possible. Two aseptic silk sutures were passed through the skin in front of the sutures, and then passed through the sutured sac. The deep sutures were passed out at the back of the scrotum over lead plates. Dry dressings were applied and silicated potash over all. The immediate effects of this operation were best studied on the dead subject. He had been able to do this in four cases. The peritoneum was found to be thrown into spiral folds radiating for several inches, and in one case extending over to the opposite side. The canal was filled by the sac. He had had personal experience of twenty-two cases, all of which had recovered, though in four cases scrotal abscesses had occurred. He had seen many cases, also, in the hands of others, but had never seen a death. In only three of his cases was it needful for the patient to wear a truss afterward, on account of slight bulging. One patient on whom he had operated had been the captain of his football team during the past winter, and wore no truss. Dr. Ball deprecated the wearing of a truss unless there was distinct bulging, as its pressure tended to produce absorption of the tissues. He believed that the only case in which operation for umbilical hernia was contra-indicated was where the abdomen was so contracted that the hernia could not be replaced within it.

Mr. Barker (London) said he had used silk in all but two cases to close the opening. Catgut was absorbable.

Dr. Kendal Franks (Dublin) said the two questions were, "Was the operation safe?" and "Was it followed by radical cure?" In his opinion it was safe when reasonable precautions were taken. A patient was not cured, though, if he had to wear a truss when making exertion. What we should aim at was to dispense with the wearing of a truss altogether. Of his own cases he had only been able to trace four in which a return of the hernia took place. He had in one case repeated the operation twelve months later. He found the inguinal canal obliterated, but a small hernia had forced itself through the abdominal wall at a higher level. It had been said that the operation should be done where the hernia could not be controlled by a truss, but he could not limit it to these, but used it in cases of small hernia. A patient who wore a truss was at the mercy of it. If such a patient were young, with the greater part of life before him, he would operate. But in an elderly man, who had worn a truss for years and been able to control his hernia with it, he would not. It was not always wise to dissect the sac off. The most important part of the operation was the way of closing the canal and rings. He had early used Wood's method, but disapproved of it.

Dr. Murphy (Sunderland) described a case in which a patient, aged fifty-six, who had suffered from hernia for sixteen years, cut it across with a razor and removed omentum, etc. The gut escaped. He was called in and completed the operation according to approved surgical methods. The patient did well.

Mr. Mayo Robson (Leeds) said he had operated in twenty-six cases. In half of these he had operated for strangulation, and in the other thirteen because the hernia could not be kept reduced by trusses. In all but two cases the sac was ligatured at its neck. Most of the patients were permanently cured, and it seemed quite unnecessary to recommend a truss. He thought the only satisfactory operation was excision of the sac after ligaturing it at the highest possible point, and if the sac were previously separated as high as possible from surrounding parts the operation was easy. He thought Macewen's plan of preserving the sac and making it act as a pad offered distinct advantages.

Professor Thornley Stoker (Dublin) remarked how practically safe the operation for radical cure of

hernia had now become. He objected to the passing of silver sutures and leaving them there as permanent sources of irritation. The plan of twisting the sac was first introduced by Dr. C. B. Ball. Two sutures—of silk or catgut—were passed between the walls of the canal and transfixed the twisted sac and maintained its twist. He preferred not to separate the sac from the deep parts of the canal. In the greater number of cases the peritoneum was not opened. He remarked that sutures were chiefly useful to provoke a certain amount of exudation. Too great an amount of tension was to be avoided.

Mr. Walsham (London) had had experience of twenty cases. Three of these were umbilical, eight femoral, and the rest inguinal hernia. In all cases he had dissected out the sac. He had only performed the operation once where the hernia was of very large size. In every case he had used catgut sutures. In early cases he had afterward used a truss, but in later cases he had not done so, and he had seen no occasion to regret not having done so.

Dr. Ward Cousins (Southsea) said the progress which had been made was largely due to antiseptics. He would operate on patients early in life. Young children bore operation wonderfully well. His plan was to expose and separate the sac and pass two sutures—one close to the external ring and the other half an inch below it. As regards trusses, he believed that a great future lay before us in seeing that they were properly applied.

Dr. Heuston (Dublin) remarked on the additional security derived from attaching the twisted neck of the sac to Poupart's ligament.

Mr. Thomson (Dublin) said that while extremely good results were got in some cases, in others the results were disappointing. In one case the hernia returned after two operations. A lax condition of peritoneum was an initial trouble.

Professor Kocher (Berne) had operated on seventy cases. He ligatured the sac, having drawn it down and cut it away.

Mr. Wheeler (Dublin) said he never used silver wire. He preferred silk, or, in children, catgut, because there was less strain on it and it was sufficient. With children antisepsis was difficult.

Sir George Porter remarked that it was an interesting fact that there were so few deaths.

Mr. Mitchell Banks replied that minor details were not of much importance. Probably the simplest operation would be the most extensively adopted.

Congenital Displacement of the Bowel.—Dr. Eustace Smith reports in the *Archives of Pediatrics* for July, 1887, the case of an infant two months old who suffered from very frequent attacks of abdominal pain followed by great prostration and dyspnœa. The bowels were relieved regularly. The pains returned with increasing frequency and violence, and the child finally died exhausted. An examination of the body after death showed all the organs to be healthy, but there was a congenital deficiency in the ligamentum arcuatum externum on the left side of the diaphragm. In consequence of this there was left a rounded opening, about one inch in diameter, through which the whole of the large bowel had passed into the left side of the thorax. The displaced portion of intestine was of perfectly normal color and appearance. The left pleura also was quite smooth, and showed no trace of inflammation. The left lung had evidently never been expanded from birth, for it lay flattened against the spine. The heart lay underneath the anterior border of the right lung, considerably to the right of its normal position. On the left side the diaphragm was quite flat, so that the spleen was pressed downward from under cover of the ribs.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 14 to August 20, 1887.

Baily, Joseph C., Lieutenant-Colonel and Assistant Medical Purveyor. Granted leave of absence for one month. Par. 10, S. O. 191, A. G. O., August 18, 1887.

Baxter, J. H., Colonel and Chief Medical Purveyor. Ordered to proceed from Washington, D. C., to New York City on public business, and on completion thereof to return to Washington. Par. 5, S. O. 187, A. G. O., August 13, 1887.

Byrne, Charles B., Captain and Assistant Surgeon, Washington Barracks, D. C. Granted leave of absence for one month, with permission to apply for an extension of one month. Par. 4, S. O. 171, Division of the Atlantic, August 16, 1887.

Dietz, William D., First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, with permission to apply for an extension of one month. Par. 7, S. O. 189, Headquarters of the Army, A. G. O., August 16, 1887.

Johnson, Henry, Captain and Medical Storekeeper. Ordered, in addition to his present duties, to take charge of the office and perform the duties of acting assistant medical purveyor in New York City during the temporary absence on leave of Lieutenant-Colonel Joseph C. Baily, Assistant Medical Purveyor. Par. 11, S. O. 191, A. G. O., August 18, 1887.

McCaw, W. D., First Lieutenant and Assistant Surgeon. Relieved from temporary duty at Fort Riley, Kan., and ordered to his proper station, Fort Leavenworth, Kan. Par. 3, S. O. 84, Department of the Missouri, August 15, 1887.

Wilson, George F., Captain and Assistant Surgeon. Granted leave of absence for fifteen days. S. O. 78, Department of Dakota, August 8, 1887.

Wolverton, W. D., Major and Surgeon, Washington Barracks, D. C. Granted leave of absence for twenty days. Par. 3, S. O. 171, Division of the Atlantic, August 16, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 20, 1887.

Gardner, J. E., Passed Assistant Surgeon. Detached from Naval Hospital, Norfolk, Va., and ordered to the Fish Commission steamer Albatross.

Martin, William, Assistant Surgeon. Ordered to Naval Hospital, Norfolk, Va.

Robinson, S., Medical Inspector. Placed on retired list.

Simons, M. H., Passed Assistant Surgeon. Appointed Surgeon from August 16, 1887.

Van Reypen, W. K., Surgeon Appointed Medical Inspector from August 16, 1887.

Acetonuria in Children.—Dr. Baginsky has published a communication on acetonuria in children. Acetone is found in the urine of some children in health, but in infinitesimal quantities. It appears in greater amount when the temperature rises in the course of febrile disease. It originates in albumen in process of decomposition. Some have affirmed that acetone causes paroxysms of eclampsia in children. It is true that an enormous quantity of acetone is found in the urine of children suffering from convulsions. It is doubtful, however, whether acetone is the cause or the effect of the eclampsia. Dr. Baginsky believes that it is the effect, for he has proved that acetone is quite harmless, if introduced into the system of a dog, either by the mouth or subcutaneously.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 32, No. 10. NEW YORK, SEPTEMBER 3, 1887 Whole No. 878

Original Articles.

SUCCESSFUL REMOVAL OF TWO OSTEOMATA OF THE ORBIT: ONE ORIGINATING IN THE FRONTAL, THE OTHER IN THE ETHMOIDAL CELLS.

WITH A HISTORY OF OSTEOMATA OF THE NEIGHBORING PNEUMATIC CAVITIES OF THE ORBIT.[1]

BY JOSEPH A. ANDREWS, M.D.,

OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK.

THE exostoses which intrude into the orbit from the neighboring cavities are very rare. In 290,579 cases of eye-disease observed at the New York Eye and Ear Infirmary since 1821, orbital exostosis occurred three times; at the Manhattan Eye and Ear Hospital, New York, two cases were observed in 73,804 cases of eye-disease; at the New York Ophthalmic and Aural Institute, it was observed three times in 65,608 cases of eye-disease; therefore, eight cases of orbital exostosis were observed in 429,989 cases of eye-disease. Many surgeons in large ophthalmic practice have never met with this disease. The number of cases of orbital exostosis recorded by foreign surgeons is small, and the results of operative treatment have been most discouraging.

I have collected all the cases of osteoma of the frontal, ethmoidal, and sphenoidal sinuses which have been recorded; and I have cited briefly those cases which have been carefully observed, because some of them furnish valuable information from a practical stand-point. They show us what we are to expect after the removal of the growths in question by a surgical operation, and some of the fatal cases suggest to us a way by which we may possibly avert the disastrous issue. The records of these cases may be tiresome reading, yet they are the only thorough basis for arguments and rules.

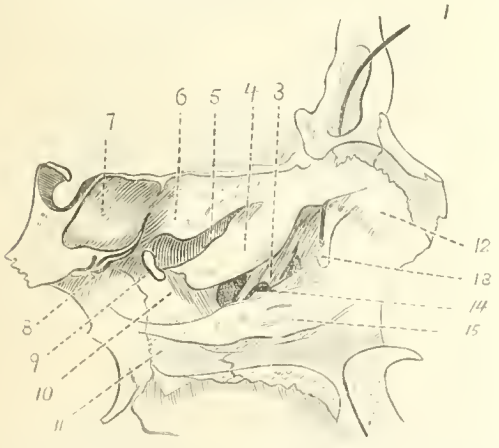

FIG. 1.—View of the Three "Meatus" of the Nose. (Holden.) 1, Probe passed through frontal sinus into middle meatus; 2, nasal bone; 3, unciform process of ethmoid bone; 4, middle spongy bone; 5, superior meatus; 6, superior spongy bone; 7, sphenoidal sinus; 8, pterygo-palatine canal; 9, spheno-palatine foramen; 10, middle meatus; 11, inferior meatus; 12, nasal process of superior maxillary bone; 13, lachrymal bone; 14, orifice of antrum; 15, inferior spongy bone.

Anatomy.—The *ethmoidal cells* contained in the "lateral masses" of the ethmoid bone consist of pneumatic spaces of variable size and number. They are divided into three sets—anterior, middle, and posterior cells—which intercommunicate. The cells on the upper surface of either "lateral mass" are roofed in by corresponding cells in the orbital plate of the frontal bone; those behind are closed by the body of the sphenoid and the orbital process of the palate-bone; those in front are walled in by the lachrymal bone; those below, by the superior maxillary bone. On the outer side of each "lateral mass" the cells are closed by a smooth, thin, square plate of bone, called the "os planum" or lamina papyracea, which belongs entirely to the ethmoid, and forms a large share of the inner wall of the orbit. The ethmoidal labyrinth (or cells) sends a pneumatic process (called, by Zuckerkandl, bulla ethmoidalis) into the middle turbinated bone, which may attain the length of twenty-six millimetres, and is capable of displacing the septum of the nose laterally.

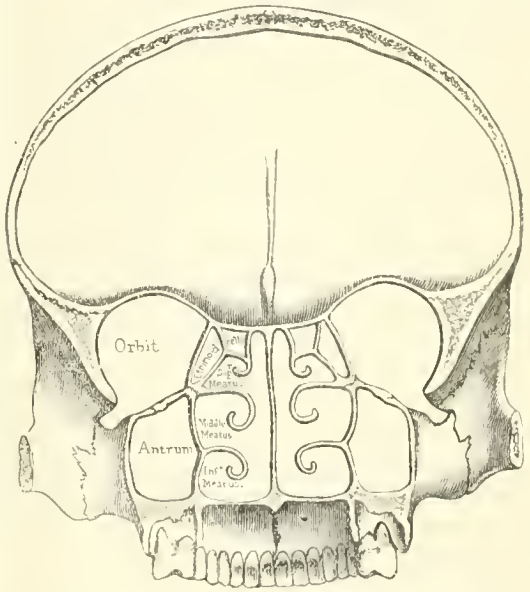

FIG. 2.—Section showing the Meatus of the Nose. (Holden.)

Two thin plates of bone stand out from the surface of the "lateral mass" which looks toward the septum of the nose, known as the "turbinated" or "spongy" bones of the ethmoid—*i.e.*, the "superior," "middle," and the "inferior" spongy bone—not belonging to the ethmoid. The spaces left between these spongy bones and the "lateral masses" are called the superior and middle "meatus" of the nose. The superior meatus, being farther back than the middle one, leads into the "sphenoidal sinus," and also into the "posterior ethmoidal cells;" the middle meatus leading into the "anterior ethmoidal cells" (distinct from the posterior) and also to the frontal sinus, along a funnel-shaped canal (the "infundibulum") which passes through the foremost of the ethmoidal cells. The ethmoid has, therefore, an important relation to the nasal fossæ. It is likewise in intimate relation to the cranial cavity, as its "horizontal plate" forms a part of the bone of the skull. The ethmoidal cells sometimes send large prolongations into the frontal bone. One of the maxillary cells of Haller, which lie in the frontal process of the superior maxilla and communicate with the ethmoidal cells, may have a very pro-

[1] Read before the Section in Surgery, New York Academy of Medicine, May 9, 1887.

nounced development, in which case the antrum of Highmore has been found to be divided into two *étages*, the upper one communicating with the ethmoidal cells (Zuckerkandl). The lateral ethmoidal cells are not infrequently so greatly developed that they appear as prominences at the inner wall of the orbit. Dehiscences occur in the os planum, orbital wall of the frontal sinus, and the antrum of Highmore. In brachycephalæ the ethmoidal cells are likely to be greatly developed (Berger and Tyrmann).

As the greater number of the orbital osteomata are found in young people, and may have developed in the first year of life, it has been assumed that they had some relation to the development of the bones.

FIG. 3.—Side View of Fig. 4. *a*, Portion in nasal fossa; *b*, orbital portion; *c*, anterior portion; *d*, posterior portion.

Development of the frontal and ethmoidal sinuses.—At birth there are no traces of the frontal sinuses. The foundation of the frontal sinuses is furnished by the cartilaginous ethmoidal cells. Dursy (*Entwickelungs Geschichte d. Kopfes*) states that the frontal sinuses develop from independent cartilaginous layers by liquefaction of the cartilage; while Steiner's (*Archiv f. klin. Chirurgie*, vol. xiii.) view is that their development is intimately connected with the cellular spaces of the anterior ethmoidal cells.

The foundation of the nose is derived from the medial, soft, later on, cartilaginous frontal process, and the two lateral processes of the superior maxilla. Two lateral curved processes start from the frontal process, from which, in turn, crooked protuberances (the future "turbinated bones" of the nose) branch off; from this frontal process also start outward and upward processes, which are the foundation of the ethmoid cells and the ethmoidal plate, and finally form the rudiments of the antrum of Highmore below. The pneumatic spaces result from the liquefaction of the cartilage, into which the mucous membrane of the nasal cavity is invaginated. The liquefaction of the cartilage begins in the posterior ethmoidal cells and in the sphenoid, already, in the fifth month of fœtal life. In the fœtus of six months, small cartilaginous processes pass from the rudiment of the ethmoidal cells into the pars nasalis of the frontal bone, which later form the frontal sinuses. Ossification begins in the ethmoid bone in the fourth month after birth. The frontal sinuses are developed in the eleventh to thirteenth year. The development of the frontal sinuses begins with development of the pneumatic spaces of the anterior ethmoidal cells; for the frontal sinuses represent only the expansion of the anterior ethmoidal cells from above (Steiner).

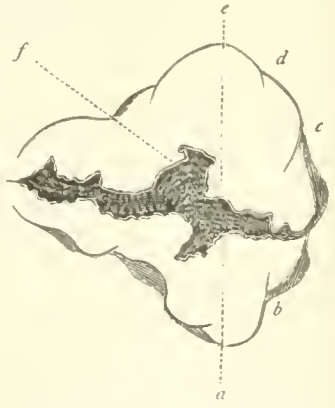

FIG. 4. — Section of Osteoma of the Ethmoid. Actual size. *a*, Sixteen mm.; *b*, portion which intruded into nasal fossa; *c*, orbital portion; *d*, compact bone; *e*, thirty-four mm.; *f*, cancellous bone.

The sphenoidal sinuses are developed before the frontal sinuses, *i.e.*, second to third year of life (Steiner). In the adult they gradually become large enough to excavate the whole body of the bone, and in old skulls the sinus often extends into part of the basilar process of the occipital bone (Holden). The anterior wall of the sphenoidal body may be entirely wanting, in which case the sphenoidal sinus would open into the ethmoidal cells. Small dehiscences have been found in the lateral wall of the sphenoid, which lead into the middle cranial fossa (Zuckerkandl). When this latter condition obtains, an inflammation in the sphenoidal sinus may readily be propagated to the dura mater.

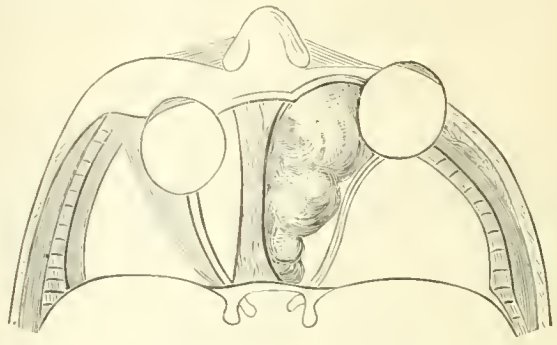

FIG. 5.—Showing Tumor in Orbit.

Bornhaupt found the anterior portion of the frontal bone solid in the third year, without the slightest trace of frontal sinuses. The adult skull which I show you is otherwise well developed, but it has no frontal sinuses; there is nothing but the diploë where the sinuses should be. In the other adult skull which I hold in my hand the frontal sinuses are enormous, but not from disease. There is a very considerable space between the two plates of bone which form the roof of the orbit, and this condition extends over the entire roof of the orbit from angle to angle.

The sphenoidal sinuses are also sometimes completely absent. In cases of extreme development of the sphenoidal sinuses, the latter may send processes into the great and small wing, the pterygoid process, the anterior and posterior, and the pars basilaris of the occipital bone (Zuckerkandl).

Then the sphenoidal sinuses may communicate with a cavity abnormally developed in the vomer (P. Langer).

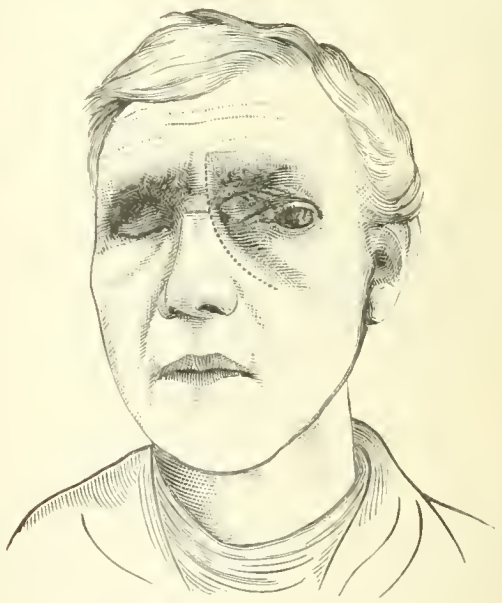

FIG. 6.—Showing Displacement of Eyeball and Line of Incision.

Virchow has directed attention to the bearing of premature synostosis of the bones of the base of the skull, especially the basal portion of the sphenoid and occipital bones, on the further development of the skull; showing that the bones of the base of the skull are thereby restricted in their development, the sella turcica being nar-

row and short, the ethmoid flat, and the pneumatic cavities narrow.

The ethmoidal cells may also be absent.[1]

Case I.—*Osteomata of ethmoidal cells.*—J. A. Andrews. L C——, aged forty-eight, mason. In September, 1886, patient was struck on his right eye with a chip of stone. Cornea sloughed. Eye became staphylomatous, and was enucleated at the New York Eye and Ear Infirmary. Left eye was injured with a chip of stone in 1883, the result being a dense leucoma of cornea. An iridectomy was performed on this eye at the New York Eye and Ear Infirmary in August, 1886, with the hope of improving the vision.[2] On examination a hard, unyielding, crescentic-shaped growth, irregular in outline, was found at the inner lower angle of the left orbit (see Figs. 6 and 7). Eyeball was displaced outward and forward and

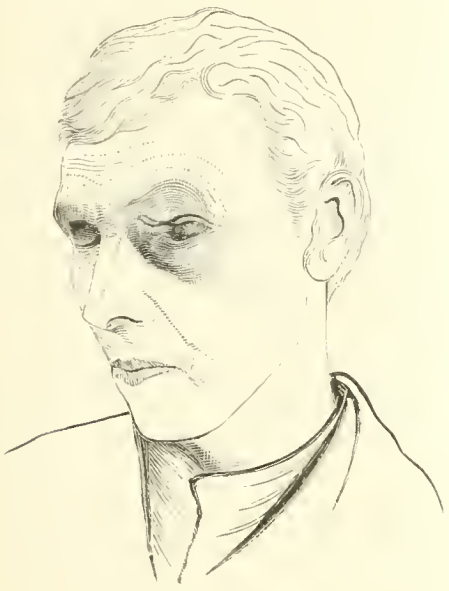

Fig. 7.

was restricted in all its movements. There was no pain in or about the growth. Patient counted fingers at two feet. Voice nasal. Was very deaf (both ears) from chronic adhesive catarrh of middle ear. There was no history or evidence of syphilis. So far as could be ascertained, the growth had existed for five or six years. Diagnosis: Osteoma of orbit; probably of ethmoid.

February 28, 1887.—Under strict antiseptic precautions the operation for the removal of the growth was performed as follows: A crescentic incision was made, from the middle of root of nose to a point just below the tumor, terminating at middle of lower border of orbit (see Fig. 6). The tumor was covered with a thin, slightly vascular membrane, which was so tense that on being incised over whole extent of growth it at once parted from the latter and exposed a nodular bony growth, which overhung the inner lower margin of orbit and passed inward to the bottom of the orbit. Having made out that the base of the tumor was composed of cancellous bone, and extended downward into the nasal fossa, the bones of the orbit, in which it was locked, were cautiously chiselled away sufficiently to loosen the growth, with the hope of then shelling it out; but the tumor extended so far into the orbit that the orbital portion was first chiselled away at its base and the remaining portions, which intruded into the nasal fossa, were removed in pieces with bone-forceps. There was considerable bleeding during the operation, but this was stopped before closing the wound. The periosteum was united with catgut sutures over the gap left in the orbit after the removal of the tumor, and the external wound with silk sutures; a small opening being allowed at the lower extremity of the wound for drainage, a piece of catgut being inserted there. The whole was covered with bichloride dressing and compression made with a bandage.

Dressing removed on March 4th, for first time. Wound had healed by first intention. Vision = $\frac{20}{200}$. Patient could now move the eye in all directions, there being no displacement of the ball. Complained of slight feeling of numbness of forehead, otherwise he feels "unusually well." In a few days patient was up and about the ward.

July 6, 1887.—Patient continues to do well.

The tumor was composed (see Figs. 3, 4, 5) of a thick shell of dense, ivory-like bone; its base being broad and made up of cancellous bone. The apex of the tumor passed back into the orbit to the sphenoidal fissure. Measurements: Antero-posterior, 50 mm.; and 50 mm. through the thickest portion.

Case II.—Bowman ("Pathological Transactions," 1859, vol. xi., p. 265) removed an ivory exostosis springing from the lamina papyracea, in a man thirty years of age. The tumor had developed during eight years, and displaced the eyeball outward and slightly forward. Ophthalmoscopic examination showed the optic disk to be as red as the rest of the fundus, and could only be recognized by the passage over it of the retinal vessels. The tumor (shown in drawing) was a nodulated, tuberous growth of solid bone. On section it was found slightly porous near pedicle, but not cancellated, and generally exceedingly dense. There was a deep groove in the tumor above, made by the superior oblique muscle. On the supposition that the tumor might possibly be an abscess or a cyst, an attempt was made to puncture it, but without success, as the tumor was evidently of a bony nature. The tumor was broken away from the inner wall of orbit by an elevator, the pedicle (by which it was afterward proved to be attached) being snapped off short. The lids became greatly swollen after the operation, but this soon subsided. In fourteen days the wound was closed and sight perfect. Two months after the operation the optic nerve was normal in appearance and eyeball natural in position and function. (See, also, specimens, "Philosophical Transactions," 1799, vol. lxxxix., p. 239.)

Case III.—Brassant (spontaneous exfoliation). The patient was a woman, sixty-five years of age. Fifteen years before, a lachrymal fistula had been unsuccessfully operated on. A bony growth, the size of a hen's egg, developed at *inner angle* of orbit, which displaced the globe entirely forward. Caustics were applied, which, in course of three to four months, gave rise to spontaneous exfoliation.

Spöring ("Abhandlungen der Königlich-Schwedischen Akademie der Wissenchaften," 1778, iv., 206; translated by Kästner). The bony tumor developed at *inner angle of orbit* in a patient twenty-one years of age, forcing the globe out of the socket. A surgeon had made an unsuccessful attempt at extraction. A peasant applied a caustic, which gave rise to intolerable pain and fainting during twelve days. The caustic was again applied, and in the following spring the tumor, the size of a hen's egg, and present for fourteen years, fell off spontaneously.

Case IV.—Lucas (*Edinburgh Medical and Surgical Journal*, 1805, vol. i., p. 405). A girl, twenty-eight years of age, received a blow from a cow's horn on the upper and inner angle of the orbit of left eye (only a contusion). At this spot a bony tumor developed, displacing the globe outward. Lucas made an incision, but no attempt to remove the growth. Nine months subsequently the tumor had become so loose that it was readily extracted. It weighed 24 Gm. The tumor was noticed a few days after the injury, and had been present for some time previous to the accident, but the connection between the traumatism and the development of the tumor was undoubtedly a coincidence.

[1] A recent publication by Berger and Tyrmann, Die Krankheiten der Keil-Höhle u. des Siebein-Labyrinthes und ihre Beziehungen zu Erkrankungen des Sehorganes, contains a very instructive chapter on the anomalies of the ethmoidal and sphenoidal sinuses.

[2] Patient was admitted to Charity Hospital, January 28, 1887.

Case V.—Maisonneuve (*Gazette des Hôpitaux*, 1863, p. 458, three illustrations). The subject of this famous case was a male, seventeen years of age. An ivory exostosis grew from the inner medial wall of the orbit; in the course of one year it filled the whole orbit, pushing the eyeball completely out of its socket. An incision was made along the inner margin of the orbit, and the growth was detached from its periosteal covering with the fingers and blunt instruments. With the same instruments the tumor was lifted from its base and removed. The eye was replaced, and gained perfect mobility and sight. Wound healed by first intention, and without fever. The tumor weighed 90 Gm.; its antero-posterior dimension was 60 mm.; its transverse diameter, 40 mm.; its vertical diameter, 70 mm.; its greatest circumference was 170 mm.; its smallest, 140 mm.

Case VI.—Maisonneuve (*Gazette des Hôpitaux*, 1853, p. 383). The growth appeared without assignable cause, at inner angle of orbit, in a man twenty-two years of age, in four months filling the medial two-thirds of the orbit and forcing the eyeball out of its socket. Maisonneuve removed the growth with hammer and chisel. Tumor weighed 28 Gm. Measurements: Sagittal diameter, 5 ctm.; transverse and vertical diameter, 4 ctm. Healing per *primam*. Function of eye completely restored (see Fig. 8, *a*, *b*).

a *b*

Fig. 8.—Maisonneuve's Case of Osteoma of Ethmoid Cells.

Case VII.—Letenneur (*Gazette des Hôpitaux*, 1871, p. 462). Woman, aged forty-nine. Tumor appeared at *inne rangle* of left orbit; filled left medial half of orbit in eighteen months. Tumor was the size of a walnut. Greatest diameter, 5.4 ctm.; consisted externally of a thin layer of compact substance; internally, of a somewhat spongy substance. Recovery, with good sight, after removal of the tumor with drills and chisel.

Case VIII.—Burow (cited by Bornhaupt, *loc. cit.*, p. 619). A bony nob, size of a pea, appeared at *inner angle of right orbit*, in a woman at the age of twenty-eight, and forced the eyeball completely out of its socket. Patient carried this growth for twenty-six years, the increase in size of which was very gradual. Four years before the operation for the removal of the growth, patient was gored in right eye by a cow; panophthalmitis and a chronic suppuration followed, gradually loosening the growth, which was readily removed. Tumor weighed 55 Gm.; was throughout ivory-like. The bony substance was rich in bone-corpuscles and Haversian canals. Measurements: Vertical, 5 ctm.; from right to left, 5 ctm.; 3 ctm. thick.

Case IX.—Tweedy ("Ophthalmic Hosp. Reports," 1882, vol. x., p. 303). The patient was a man twenty-five years of age. Left eyeball had been prominent for two years before patient consulted Tweedy. No pain in eyeball itself or in the parts around it; the globe was pushed downward and outward. The tumor was of bony hardness, occupying the *inner* part of the orbit from mid-orbital ridge to the situation of the lachrymal sac. Movements of the globe not much restricted. Vision of left eye = $\frac{20}{20}$, notwithstanding the presence in this eye of a well-marked optic neuritis, characterized by great œdema of the disk and enlargement of the veins. Vision of right eye, normal. An incision, one and a half inch long, was made through the skin and orbicular muscle, along the superciliary ridge and opposite the base of the tumor. The tumor was semiglobular in shape, and filled the upper and inner part of the orbit in front, and extended backward as far as the finger could reach. The periosteum was incised close to the orbital margin, and stripped off the tumor from before backward by means of a raspatory. Several ineffectual attempts were made to penetrate the base of the growth, but the bone was so hard that no impression could be made on it; the edges of the chisels were soon spoiled; Tweedy then used drills. Thus the orbital portion was removed; the remaining portion of the tumor was not removed because of the length of time the operation had lasted (two hours). Patient did well, and, a week after the operation, got out of bed and seemed to be in perfect health. Three weeks after the operation there was scarcely any discharge from the wound, and no pain or discomfort. Exophthalmos remained unaltered. Patient continued to do well until the morning of September 2d, just four weeks after the operation, when he complained of pain on the top of the head. Temperature suddenly rose to 102° F., and pulse went up to 80°. These symptoms increased rapidly, unconsciousness set in, and the patient died on the following day, September 3d.

The necropsy showed general basilar meningitis, with lymph in the fissure of Sylvius and at anterior part of pons Varolii. The brain in immediate contact with the tumor was in a state of red softening, being semifluid, with some puro lymph on its surface at the summit of the bony mass. Left optic nerve was stretched across a groove in the tumor at the posterior part. The greater part of the tumor was in the left anterior cranial fossa. It originally sprang from the frontal sinus and had grown chiefly upward. The roof of the sinus in part extended over the tumor, and had been in part absorbed by it. There were a few semitransparent polypoid growths in the frontal sinus. The tumor reached one inch above the orbital plate of the frontal bone, and extended for that distance into the left anterior lobe of the brain. The tumor measured, from before backward, two inches; it also sent processes, half an inch long, downward into the left nasal cavity; backward it had forced its way into the inner end of the great sphenoidal fissure.

Case X.—Busch ("Chirurgisch Beobachtungen," 1854, s. 22). Woman, thirty years of age; at age of eleven a hard growth had appeared at inner angle of right orbit. In nineteen years the growth had increased so much that it filled the entire orbit, displacing the eyeball *upward* and *forward*. Busch sawed a groove around the base of the tumor, into which he passed a chisel, and easily detached the growth. *Upward* and inward a portion of the tumor remained, which Busch treated with the actual cautery. Tumor was externally ivory-like; internally, spongy. Healing by granulation.

Case XI.—Knapp (*Archives of Otology*, 1884, vol. xiii., p. 51). A woman, forty-seven years of age, consulted Knapp for nasal polypi and orbital tumor (on nasal side of orbit), as large as a cherry, of bony hardness, and immovably connected with the os planum. Eyeball was slightly displaced, but otherwise not affected. The amount of polypi removed by snare was sufficient to fill a three-ounce bottle. A curved incision was made from the junction of the middle and inner thirds of the brow along the orbital margin, toward the nose, down to the inner lower corner of orbit, which exposed an ivory tumor piercing the os planum. The tumor was removed with chisel and mallet. Frontal sinus was very considerably enlarged, and contained a mucous polypus. Death occurred on the fourth day after operation from acute purulent septo-meningitis. *Ethmoid cells*, on both sides, were filled with polypi in all their numerous recesses. Tumor measured 15 mm. at its base, 27 mm. vertically at its orbital end, and from 12 to 15 mm. antero-posteriorly.

Case I.—*Osteomata of the frontal sinus.*—Andrews, J. A. Mary L. H——, aged nineteen, consulted me in the spring of 1883. She had felt a small hard swelling, about the size of a pea, at the inner angle of her left orbit about one year before. There never had been any pain in this region; she had simply felt the slight swelling in the region indicated, and as there was nothing like it on the other side, she "thought she would consult a doctor about it." The movements of the left eyeball were normal. Vision was likewise normal. At the inner upper angle of the orbit could be felt a small hard prominence, about half the size of a Lima-bean. It occasioned no deformity and was painless. The diagnosis of orbital exostosis was made, and, from the situation of the growth, it was suspected to spring from the frontal sinus. Based on the knowledge that exostosis of the frontal sinus may be of large size, even where the orbital portion is still quite small, the patient was advised to undergo an operation for the removal of the growth at once. Six weeks subsequently the operation was performed in the following manner:

Fig. 9.—Author's Case of Osteoma of Frontal Sinus. Actual size.

The parts about the eye were washed with plain water. A curved incision was made from the inner third of the superciliary arch, along the margin of the orbit below the eyebrow, to a point just opposite the insertion of the internal canthal ligament. On reaching the tumor it was seen to be covered with a thin, slightly vascular membrane, which parted from the bone immediately upon being incised over the full length of the growth. The tumor was very hard, the size of half a Lima-bean, and seemed to spring directly from the wall of the orbit; but on stripping the periosteum from the base of the tumor, a flat probe could be inserted between the tumor and the wall of the orbit, giving the impression of a constriction at this point. I drilled (Archimedean drill) into the neck of the growth, and determined that this portion was not made up of cancellous bone-tissue, but was compact bone. I next made out that this orbital growth was only a portion of a growth which seemed to occupy the frontal sinus, this being determined by means of a fine probe passed between the neck of the growth and the wall of the orbit, through a small hole which I made in the latter for this purpose. I next proceeded to expose the tumor by cautiously chiselling away the bone surrounding the anterior superior portion of the tumor, just below the pulley of the superior oblique muscle, carefully avoiding that important part, and made sure that I was entering the frontal sinus. This having been done, a probe showed that the tumor extended upward and backward. I freed the growth from the lachrymal bone and os planum by attacking those bones with the chisel and mallet. I next raised the tumor from its bed with bone-forceps, and carefully detached it from the soft parts with blunt-pointed scissors.

The whole mass was then removed without any further difficulty. In rotating the tumor in the frontal sinus, I must have severed its connection with the frontal bone, for there was a fresh rough spot on the tumor, and also on the septum of the sinus, evidently the seat of attachment of the growth.

I found that I had destroyed a large portion of the os planum. The periosteum was stitched over the gap in the bone with catgut sutures, and thread sutures were applied to the wound in the skin. Healing took place by first intention, and patient has continued to do well ever since.

The tumor was oblong and nodular, and composed throughout of ivory-like bone. Measurements: Longest diameter, 42 mm.; through centre, 30 mm. (see Fig. 9).

Case II.—Hilton ("Guy's Hospital Reports," 1836, vol. i., p. 493, illustration) describes the case of a woman, aged thirty, in whom a large bony growth had developed between the nasal and orbital cavity, on the left side, which had destroyed the eyeball. The growth made its appearance when the patient was thirteen years old; seventeen years later, the tumor *became loose through suppuration and fell off.* The turbinated and cellular apparatus on the left side of the nose was destroyed; the septum nasi was pushed toward the right side, obliterating the right nostril; the left orbit was forced outward. The inner wall of the orbit was next displaced and pressed upon the eyeball, which yielded to the pressure and burst. The tumor did not extend backward toward the pharynx. The whole mass sloughed away, neither pain nor bleeding attending the separation; but a large chasm was left, which opened posteriorly into the pharynx, being bounded below by the nasal surface of the hard palate and floor of the left antrum Highmori, above by the left frontal sinus and left half of cribriform plate of the ethmoid bone, internally by the septum nasi, which presented a concave surface with a small opening through it, a lower part communicating with the left nostril, and externally by the left orbit. There remained an opening in the face, previously occupied by the tumor, exposing the pharynx and hard and soft palate. The tumor weighed $14\frac{3}{4}$ ounces. Its greatest circumference measured more than eleven inches, and its least, nine inches.

Case III.—Middlemore (cited by Demarquay, "Traité des Tumeurs de l'Orbite," p. 63) attempted to remove from a woman of twenty-eight a bony tumor, situated at the superior inner angle of orbit, almost filling entire orbit, displacing eyeball completely outward, but without disturbing its vision. Tumor was covered with periosteum. Did not succeed in extracting tumor; the wound suppurated, and nine months later the tumor was loose and removed without difficulty. Dimensions of tumor: Length, $1\frac{1}{2}$ inch; circumference, $2\frac{5}{8}$ inches; weight, $1\frac{1}{4}$ ounce. Recovered.

Case IV.—Hutchinson ("Illustrations of Clinical Surgery," 1875, fasciculus i., pl. i., p. 9). The patient was a woman, aged fifty, under the care of Mr. Borlase Childs in 1859. The history showed that the tumor began to grow in early life, and had projected first from the nasal side of the orbit. The eye had been destroyed by the large nodular mass of ivory-like bone, which filled the orbit and projected over the cheek; the tumor was quite bare of soft tissues; it had undergone necrosis and become loose (see Fig. 10). At the operation the tumor was found

Fig. 10.—Hutchinson's Case.

to be movable, having no bony connections, being simply embedded in the distended orbit. The walls of the orbit had been destroyed by absorption, and nothing but fibrous structures (dura mater) separated the mass from the brain. The orbit was greatly enlarged, and would have contained a fist. The frontal sinus on the right side appeared to have been destroyed, and two fistulæ passed above it and

opened near the middle of the forehead. At the operation, Mr. Childs did not succeed in getting at the base of the tumor, but sawed off all that projected. Its structure was so hard that several saws were broken. Hutchinson thought that it was the violence done to the growth at this operation which led to its subsequent necrosis and separation. After removal the patient did well, and the cavity underwent considerable diminution.

Case V.—(*Ibid.*, p. 10).—Patient was a young man. The tumor in the frontal sinus intruded into the orbit, displacing the eye downward and outward. Hutchinson trephined frontal sinus and cut away its walls, exposing a large white ivory-like growth, much nodulated on its surface. The pedicle was broken through without much trouble, and the mass was taken away. Good recovery ensued; but two years later the man again applied to Hutchinson on account of a similar growth on the opposite side; and in removing this the dura mater behind the mass sustained slight injury, and death followed. Absorption of the posterior wall of the frontal sinus had been induced, leaving nothing but dura mater.

Case VI.—Paget ("Surgical Pathology," p. 535; specimen in the Museum of St. Bartholomew's Hospital, Series B, No. 316). Patient was a girl, aged twenty. Showed exophthalmos, due to a bony growth projecting at the anterior *upper and inner angle of orbit.* It had been observed protruding from the eye for three years, regularly increasing, and producing severe pain in the eyeball and about corresponding side of the head and face. A portion of the growth was sawed off with great difficulty. The partial removal of the tumor was undertaken, with the hope that the disturbance of its growth might lead to its necrosis and separation. The patient died from suppuration in the membranes of the anterior part of the cerebrum.

Case VII.—Turner (Preparation 546, Anatomical Museum of University of Edinburgh). The bony growth found scarcely any external projection above the orbit, although it projected into the inner wall of this cavity. The frontal sinus was much expanded, and opened by a large aperture into the roof of the orbit. Appears to have sprung from the inner table of the orbital plate of the left frontal bone, and caused a considerable indentation in the anterior end of left frontal lobe of the cerebrum.

Case VIII.—Arnold (*Virchow's Archiv*, 1873, Bd. lvii., p. 148). Case of a man, aged twenty-four. The tumor had grown steadily for five years, and first made its appearance on the forehead above the nose. At the time of the operation the tumor was hard and nodular, occupying the middle of the forehead from the hair to the root of the nose, and filled the greater part of the left orbit. The base was as large as the palm of the hand, and was surrounded by a bony ridge. There were soft places on the upper periphery of the tumor. At the places which, on palpation, seemed soft were translucent, very vascular gelatinous bodies (cysts) the size of a pea—especially numerous at periphery of growth.

The anterior wall of the frontal sinus was first disturbed, so that the tumor, the size of a hen's egg, projected above the plane of the middle of the frontal bone; on the left side it had also broken through the roof of the orbit, lachrymal bone, and the os planum of ethmoid bone, and passed into the orbit at these parts. The greater part of the bony septum of the nose on the right side, and on the left side the upper middle turbinated bone, were destroyed by the pressure of the growing tumor. The anterior portion of the lamina cribrosa, the perpendicular plate of the sinus of ethmoid, were also disturbed by the growth of the tumor, which here projected through several openings into the posterior, *i.e.*, upper wall of the frontal sinus, into the cranial cavity. There was no visual disturbance. Professor Simon removed the prominent part of the tumor on a level with the anterior surface of the frontal bone with the saw and chisel, and some of its processes were removed with bone-forceps. Patient had high fever during first three days after the operation; felt easy for next week. On the twelfth day after the operation brain symptoms set in—delirium, paralysis of some cerebral nerves, deep coma, and death. The autopsy showed that a portion of the tumor had been left projecting from the posterior face of the frontal bone into the cranial cavity. Both frontal sinuses were immensely distended. There was purulent meningitis and abscess in the left frontal lobe, which had perforated into the left lateral ventricle. The tumor was composed wholly of bone-tissue, and in its peripheric parts it was very compact and ivory-like; in the deeper parts more spongy, and quite rich in diploëtic substance. The tumor was covered with a delicate membrane. The dimensions were: Vertical, 90 mm.; transverse, 75 mm.

Case IX.—Badal ("Bulletins et Mémoires de la Soc. de Chir. de Paris," 1884, tome x., p. 603; reported by M. Chauvel). The patient was a man aged twenty-four. A hard tumor appeared in 1880 at supero-internal angle of right orbit; had progressed slowly during two years, and resisted all medication. In 1882 there was an enormous exophthalmos, with epiphora and intense conjunctivitis. Vision reduced one-third; diplopia; discoloration of optic disk. The tumor wholly filled right orbit. No history of syphilis; no pain. Removed tumor with chain-saw, elevator, and bone-forceps. Tumor measured 35 mm. in height, 40 mm. in depth, 60 mm. in breadth. It presented numerous prolongations toward ethmoidal cells, sphenoidal fissure and spheno-maxillary fissure, and superior portion of orbit. The surface was irregular, mammillated, and its numerous projections lodged in the neighboring cavities, perforating or destroying the bony walls of the orbit. The brain was exposed at one point, and a portion of the cerebellar matter followed the ablation of the tumor.

The operation lasted an hour and a half; one hundred and fifty grammes of chloroform were used; and a good deal of blood was lost at the operation. Operation was followed by congestion of lungs. No local reaction. Healing assured on the fifteenth day, when the eye had recovered a part of its movements, but there was still an absolute paralysis of accommodation, and the acuity of vision was not restored. At the end of one year diplopia had disappeared.

Case X.—Knapp (*Graefe's Archives*, 1861, vol. viii., p. 230). The patient was a boy aged fourteen. The exostosis extended from the roof of the orbit toward both the orbital and cranial cavity. It had steadily and perceptibly grown for two years, producing exophthalmos, and, ultimately, repeated attacks of an irritative cerebral affection, which lasted six weeks. Knapp succeeded in removing, with Heine's saw, only a part of the orbital portion of the tumor. Moderate suppuration set in. The patient died eleven weeks after the operation, *from purulent meningitis.* The entire tumor was a round, nodular, ivory-like exostosis the size of a goose-egg, which filled part of the ethmoid cells, the left frontal sinus completely, the right partially, in two small places perforated the anterior table of the frontal bone, and very extensively the upper posterior table, occupying the whole left and a part of the right anterior cerebral fossa, and nearly one-third of the left middle fossa.

Its diameters were 59 mm., 56 mm., and 54 mm., respectively. It was covered everywhere with a thickened capsule of periosteum, in which, he states, he was able to follow the direct formation of bone from connective tissue.

Case XI.—Knapp ("Tr. Inter. Ophthal. Congress," 1876, p. 52). The patient was a man aged thirty-six. Nineteen years before seen by Knapp patient first noticed a hard swelling at the root of his nose, which slowly but steadily increased until it attained the size of a small apple, situated on the root of the nose, and sending a prolongation the size of a walnut into the inner wall of each orbit, crowding the eyes toward the outer walls of their sockets. There had never been pain, disturbances of sight, nor other inconvenience connected with the tumor. The tumor was removed piecemeal with the chisel and

mallet, the body of the growth being thus attacked with these instruments. There was some suppuration in the right corner of the wound, but it gradually ceased, and the patient was discharged, cured, four weeks after the operation.

Case XII.—Roux ("Mémoires de l'Académie Royale de Médecine," 1871, I., iii., p. 4) attempted to remove an exostosis of the right frontal sinus, but could not complete the operation, and the young man died. The specimen was removed by Nélaton and deposited in the museum of the Val-de-Grâce Hospital.[1]

Case XIII.—Jobert (*ibid.*, p. 18, and Pl. ii., Figs. 1 and 2) made an unsuccessful attempt to remove an exostosis of the frontal sinus with the trephine. In spite of its great dimensions, the tumor did not adhere at any point to the cranium, but it was firmly wedged in the region which it occupied. Jobert thought that the extreme development of the growth made its successful removal almost impossible. At one point (very limited) the tumor seemed to blend with the frontal face of the sinus. Dimensions: Height, 50 mm.; length, 40 mm.; antero-posterior measurement, 30 mm. Irregular surface. Tumor occupied anterior cerebral fossa. Fatal.

Case XIV.—Dolbeau (*ibid.*, p. 12). The patient was a man aged twenty-one. No syphilis. For three years deformity in right fronto-orbital region. Tumor presented at *inner upper angle of orbit*, and pushed the *eye outward* and *downward*. At the end of three years he became subject to pain in right side of head; noticed at same time augmentation of volume of frontal region (slow but progressive). No convulsions nor paralysis. The *orbit was invaded only ten months before the operation.* An incision was made near to and parallel with the median line, then a horizontal one along the upper orbital margin. The opening in the frontal bone through which the tumor had intruded into the orbit was enlarged, and the tumor, which was loose in the frontal sinus, was seized with bone-forceps, a piece of it being broken off; it was then seen that the tumor was composed of a bony shell of ivory hardness, with cancellous vascular tissue in the interior. The remainder of the growth was removed piecemeal with bone-forceps. The last portion removed seemed to indicate that the tumor was implanted into the septum of the frontal sinus. On smoothing this small rough surface with the rongeur, an artery (A. nutritiva) spouted and had to be obliterated with a globule of wax. A pledget of lint was placed in the cavity of the sinus, the flap of skin put in place, and covered with a wet compress. The operation was followed by ecchymotic swelling of the lid of right eye and headache. On second day headache increased, and there was some delirium; pain in the region of the *left* frontal sinus, and œdema of the eyelids on this side. Suppuration commenced on third day; on fourth day cephalalgia was very intense, chiefly in occipital region, and patient was slightly somnolent. No vomiting. Patient did not begin to improve until ninth day. Got up on nineteenth day, and was discharged, cured, thirty-one days after the operation. The movements of the right eyeball were normal, vision intact, but the globe had not completely returned to its normal position, as it was situated on a lower plane than that of left eye. The operation was completely successful. The tumor was formed of a shell of compact bone-tissue, its interior filled with spongy bone-tissue. No trace of a capsule of cartilage.

Case XV.—Banga (*Deutsch. Zeitschr. f. Chirurgie*, 1874, iv., p. 486). A youth, aged eighteen, had received a blow on the left eye with the handle of a whip, six years previous to his consulting Professor Socin, in Basle. Three years later he first noticed that his left eye was *swelled*, and was more prominent than the right, which continued without pain until his visit to Professor Socin's clinic, at which time the left eye was pushed forward, downward, and outward by a hard tumor at the upper orbital margin. Left upper eyelid was greatly swelled and discolored from distended veins, and covered the tumor entirely. The tumor was hard as stone, immovable, and painless, with a horizontal diameter of 5.0 ctm.; vertical, 4.5 ctm.; conjunctiva, bulbi, and palpebrarum only slightly injected; cornea slightly cloudy hence a good ophthalmoscopic examination was not obtainable. Vision, L. E. = $\frac{1}{20}$. Excursion of the eyeball restricted to slight elevation, rotation, and downward motion. Eyelids almost immovable. Vision of R. E., normal. The conjunctiva became slightly injected as soon as right eye was uncovered; however, the right eye became more injected, and watered. No cerebral symptoms; also no signs of growth of tumor into nasal cavities. At the operation, Professor Socin found that the superior oblique muscle had made a groove into the tumor. The tumor was readily loosened with mallet and chisel and lifted out with bone-forceps. Roof of orbit was intact. Exophthalmos was reduced to about one-third of its previous amount. Ice-bladder applied over the wound. In first week there was little reaction; secretion moderate. On eighth day, intense headache, chilliness set in, with subsequent high temperature, debility, violent and persistent vomiting, great anxiety, convulsions, sopor, and two days later, on tenth day after operation, death. Autopsy showed diffuse purulent meningitis, particularly in anterior part of left hemisphere. In centre of base of left frontal lobe was an abscess in the brain the size of a pigeon's egg, surrounded by punctate hemorrhages. Dura thickened, covered with discolored pus. The extirpated tumor was very hard, and the size of a hen's egg; weight, eighteen grammes. The surface of the tumor was in part smooth, in part finely porous on the surface, like pumice-stone, and covered on all sides with periosteum. Tumor consisted externally of ivory-like substance, internally of cancellous tissue filled with a vascular, fatty pulp. Anteriorly, the floor of the frontal sinus is absent on left side. Microscopically: The ivory part of the tumor consisted of symmetrical bony tissue, with few Haversian canals, interlamellar substance, and a few bone-corpuscles. Inward and upward, close to the infundibulum, was a rough place on the frontal bone corresponding to a similar one on the tumor, where the tumor with a narrow pedicle was believed to have originated.

Case XVI.—Arnold (*Virchow's Archives*, vol. lvii., p. 146). The growth showed itself by a small prominence at the inner angle of the left orbit, where there was a short fistulous ulcer secreting at times some thin pus. Left frontal sinus was completely filled with a tumor which had destroyed a part of its anterior wall and the anterior half of the roof of the orbit. The tumor was fixed on the posterior plate of the frontal sinus. It was nodular and slightly movable, measuring, laterally, 4 ctm.; antero-posteriorly, 3.5 ctm.; vertically, 2.5 ctm. It was covered with a delicate connective-tissue membrane. The edges of the bones perforated by the tumor were sharp and jagged, the result of the destruction from pressure by the growth. The cause of death is not given. The history is defective.

Caspar Hoppe (quoted by Bornhaupt, *loc. cit.*, p. 601). Busch operated on a female, aged twenty-two, in whom, seven years before, a bony tumor had developed immediately above the root of the nose under ordinary symptoms of osteoma of frontal sinus. The tumor was removed, but death ensued thirteen days after the operation from abscess of the brain. The tumor filled both frontal sinuses and the ethmoidal cells, and a portion the size of a pigeon's egg projected through the anterior cranial fossa into the cranial cavity.

Case XVII.—Bryant (*British Medical Journal*, 1872, vol. ii., p. 631). The patient, a man, aged twenty-four, first observed a slight protrusion of the right eyeball five years before, which had slowly but surely increased. Bryant first removed the growth from the orbit by turning down the eyeball and its appendages, and then chisel-

[1] See Pl. II., Figs. 3 and 4, Dolbeau, Mémoires de l'Académie Royale de Médecine, 1871.

ling and sawing it away piecemeal. Its aggregate size in the orbit was that of a small orange. He then removed the exostoses from the frontal sinus in the same way. The growth appeared to arise by a pedicle from the anterior plate of the frontal bone. The result of the operation is not given.

Case XVIII.—Adelmann ("Beiträge zur med. und chirurg. Heilkunde," Bd. ii., s. 172, quoted by Bornhaupt, p. 601). Patient was a woman, aged twenty-three. Tumor partially removed. Meningitis on fifth day after the operation, from which she recovered, and left the hospital six weeks later, with a fistula.

Case XIX.—Birkett ("Guy's Hosp. Reports," 1871, p. 505, plates i., ii., iii.). Patient was a girl, aged fifteen. When thirteen years old, patient had scarlet fever six weeks, after which her friends noticed a swelling on the forehead, but the girl herself stated that an altered position of the left eyeball first attracted her attention and that the frontal swelling appeared subsequently. The displacement of the eyeball had existed only about nine months prior to the operation.

The left upper eyelid was depressed and could not be perfectly raised, and the fissure between the lids inclined obliquely downward and outward. The left eyeball was on a lower plane than the right; it was also everted. The veins on the surface of the upper eyelid were dilated and the cutaneous surface congested. The tumor spread into the angle of the orbits, on both sides of the root of the nose, but projected most into the left. In the centre of the frontal swelling fluctuation could be felt. On exposing the tumor, Birkett found a defect in the frontal bone. The tumor sprang from the posterior wall of the sinus. The operation was not completed for fear of opening the cranial cavity. Patient died thirty-eight days after the operation, of purulent meningitis. The tumor extended transversely and antero-posteriorly into the middle of the anterior fossæ of the cranium, hiding the crista galli. Dura mater was united very firmly to one portion of the growth, and on the right side, the brain also. There was an abscess (chronic) in the anterior lobe of the left hemisphere. The left orbital plate of ethmoid bone was destroyed; the right orbital plate of the ethmoid bone was entirely gone, and so the right frontal sinus was laid open and a piece of the bony growth exposed to view in the right orbit. The growth was composed entirely of the finest and most delicate cancellous bone-tissue.

Case XX.—Öttingen ("Mittheilungen aus der chirurg. Abtheilung der Universitätsklinik zu Dorpat, 1858," in den Beiträgen zur Heilkunde, herausgegeben von der Gesellschaft prakt. Aerzte zu Riga, 1860, Bd. iv., Tfl. 5). A man, aged twenty-four. When twenty-one years old a bony tumor appeared at upper medial angle of right orbit, by which the eyeball was displaced forward, downward, and outward. Öttingen removed a portion of the tumor, and succeeded in replacing the eyeball, but the patient died in twenty-nine days after the operation, of purulent meningitis.

Case XXI.—Hewitt ("St. George's Hospital Reports," 1867, vol. ii., p. 14). Case of Lawrence. The tumor appeared to be limited to the inner part of the orbit, but after death dissection proved that the frontal sinus was filled with the growth, which had, moreover, made its way into the cranial cavity.

Case XXII.—Hewitt (*ibid.*, p. 17). A woman, aged twenty-four, had had exostosis of frontal sinus for several years, situated at the lower part of the forehead and accompanied by head-symptoms. Removal attempted by Professor Regnoli, of Pisa. At the operation, the anterior table of the frontal bone and corresponding parts of the nasal bone and of the ascending process of the superior maxillary, also affected by the exostosis, were removed at the same time. The actual cautery was then applied, necrosis followed, and the dura mater was laid bare. Nineteen months afterward the patient was completely cured.

Case XXIII.—H. A. Lediard (*British Med. Jour.*, 1882, ii., p. 1252). A sailor, aged thirty-three; tumor said to have been the size of a pea at birth, and was situated between the upper eyelid and eyebrow. Tumor gradually enlarged, inducing destruction of the globe at the age of nine years. The tumor ceased to enlarge at the age of twenty-five, and two years later the skin which had hitherto covered it suddenly gave way. When admitted to the hospital, at the age of thirty three, the tumor was 4.5 by 5 inches, weighed 2.25 ounces; was pediculated; tumor was movable, and an offensive discharge issued from its base; a month later the whole mass became suddenly detached without associated pain or hemorrhage. (Frontal sinus?)

Case XXIV.—Panas (*Arch. d'Ophth.*, tom. iv., p. 289). A girl, aged eighteen; the exostosis of the right orbit made its first appearance when she was thirteen. It had already been subjected to two operations. The tumor, the size of a hen's egg, occupied the region of the right eyebrow, and extended to the left eyebrow and to the bridge of the nose. The eye was pushed very much forward, downward, and outward, and possessed merely quantitative perception of light. The optic papilla was atrophic. The sense of smell on the right side was blunted. No cerebral symptoms. Panas made a broad opening in the frontal sinuses, but had to be satisfied with resection of the orbital part of the tumor, since the entire frontal sinus was filled with compact bony tissue. Death followed six days later from meningitis, caused by purulent phlebitis. The neoplasm originated in the orbital wall of the frontal sinus, and extended into the orbit, the ethmoid bone, and the frontal sinuses of the opposite side, and then into the cranial cavity.

Case XXV.—Knapp (*Archives of Oph.*, 1880, p. 464). The patient was aged forty-eight. Inner part of upper lid slightly prominent and pushed down; conjunctiva and eyeball normal; mobility unimpeded; vision and ophthalmoscopic condition normal. In inner upper corner of orbit there was a tumor nearly as large as a flattened hazel-nut, slightly uneven, abruptly rising from orbital wall and immovable. Curved incision was made from middle of superciliary arch along the lower margin of the brow, down to insertion of inner canthal ligament. The stretched periosteum of tumor parted on being divided, and exhibited the yellowish, shining surface of the tumor, which was of uniform hardness. The tumor showed a slight constriction at its base. Knapp cut a furrow along the supposed cancellous base of tumor with chisel and hammer, and as it did not become loose or movable, Knapp chiselled a regular groove into it ten millimetres deep and twenty-five millimetres in length along the wall of the orbit. Persistent chiselling for three-quarters of an hour showed that he was not reaching the supposed cancellous base, but was carving a furrow into the uniformly compact mass of the tumor itself. It was then evident that the tumor extended beyond the limits of the orbit into the nasal fossæ, the frontal sinus, and, perhaps, the cranial cavity. Being all around in connection with the bony wall of the orbit, and supposing the tumor to have originated in the diploë, Knapp broke down its osseous surroundings with the chisel, the edge of which was held perpendicularly to the wall of the orbit, enclosing the tumor. This was begun at the upper edge of the tumor and close behind the supra-orbital notch, avoiding interference with the pulley of the superior oblique muscle; then along the circumference of the tumor, breaking down the bony plate of the orbit as far as it encased the growth. Having done this from the superciliary notch along the upper inner corner of the orbit down to middle of anterior part of os planum, the tumor became loose. Knapp next carefully detached all the soft parts from the tumor. Having done this on all the surfaces of tumor, the latter lay completely loose in its periosteal envelope, and was drawn out with bone-forceps.

On examining the wound with the finger, the upper

half of the os planum and the whole anterior upper inner half of the roof of the orbit were absent; the upper part of the nasal cavity and the whole right frontal sinus lay open, and in the outer part of the roof of the orbit a triangular piece of bone was fractured and freely movable, but was kept in its natural position by the periosteum and dura mater. The fractured bone was not disturbed. The dilated frontal sinus and the opened nasal cavity were found free from other growths. The wound was united by silk sutures, the threads being passed through the skin and periosteum on both sides. At the lower end of the wound, immediately above the internal canthal ligament, a silver drainage-tube was inserted and a charpie bandage applied. The wound healed by first intention. There was no diplopia, and the movements of the eye were natural. The tumor was oval, the size of a large English walnut. Vertical diameter measured 36 mm.; its greatest antero-posterior diameter, 29 mm.; its greatest lateral diameter, 24 mm. Surface uneven, with several nodular projections.

Case XXVI.—Kundrat (*Wiener med. Blätter*, 1883, No. xlviii.). The tumor extended far into the cranial cavity, therefore it could not be removed. The necropsy showed that the tumor had originated from the region of the lamina cribrosa and the superior inner angle of the roof of the orbit.

Case XXVII.—Demarquay ("Annales de la chirurgie française et étrangère," t. iii., p. 242). An ivory exostosis, adherent to the anterior plate of the frontal bone, on right and left side. The frontal sinuses had been opened by suppuration. The tumors were complicated with suppurations and polypi. Successfully removed.

Case XXVIII.—Heister ("St. George's Hosp. Rep.," 1867, vol. ii., p. 14). A soldier, aged thirty-three, had on his forehead an enormous exostosis, which was increasing in size. Heister attacked it with hammer and gouge, and brought it away, extensively laying bare the dura mater, notwithstanding which the patient ultimately *recovered*.

Case XXIX.—Massey (*ibid.*, p. 18). An ivory exostosis, three inches long and one and one-half inch broad, was removed by Massey from the middle of the lower part of the frontal bone. The tumor was laid bare and a groove made around its base with Hay's saw, after which, by means of a chisel and gentle blows with the mallet, the whole growth was removed bodily. Wound healed perfectly within eight days.

Case XXX.—Paget ("Surgical Path.," p. 534, specimen in Museum of College of Surgeons, London, No. 795, pictured in Baillie's Morbid Anatomy, fasc. x., pl. i., fig. 2). Tumor was two and one-half inches in diameter, deeply lobed and knotted; filled frontal sinuses and upper part of left orbit, encroaching upon the right orbit, and projecting for nearly one inch on both the surfaces of the skull. In its growth it displaced and destroyed by pressure the adjacent parts of the tables of the skull and the wall of the orbit. The tumor was for the most part hard as ivory, but in its central posterior portion it was composed of very close cancellous tissue.

Case XXXI.—Bornhaupt ("Archiv f. klin. Chirurgie," 1881, Bd. 26, p. 595, Figs. 1, 2; pl. xi.). Girl, aged eighteen. Two years before seen by Bornhaupt, simultaneously with beginning of menses, the left eye began to lachrymate, and, unattended by pain, to be protruded from the orbit, and diplopia set in. A few days before consulting Bornhaupt a phlegmonous process developed in the orbit. The upper eyelid and the region of the inner angle of the orbit were especially swollen, and there was fluctuation in the depth of the orbit. An incision four centimetres long was made at the inner angle of the orbit, and parallel to the orbital margin, by which muco-purulent material was evacuated; the bone was laid bare, and nodular masses of bone thereby exposed, showing that there was unquestionably a bony tumor. On June 19th the left upper eyelid was very red and œdematous, and left eyeball displaced forward, downward, and outward. Vision, L. E., $\frac{1}{4}-\frac{1}{3}$ of normal. No defect in visual field. Ophthalmoscope showed congestion of retinal circulation, inflammatory opacification of papilla and para-papillary tissue of retina. The movements of the eyeball were restricted in all directions; the superior rectus seemed most affected. Under treatment with lead-water applications and washing out with a solution of carbolic acid, the swelling of the upper lid subsided, so that firm, nodular bony masses could be felt in the medial half of the orbit, making the diagnosis of an orbital osteoma certain. July 2d, the phlegmonous process exacerbated, so that near the former fistulous opening a puncture had to be made, giving exit to a bloody, muco-purulent fluid. The wound was drained just so soon as the inflammatory phenomena had subsided. Volkmann operated, July 16, 1880, for the removal of the growth. He made a curved incision along the orbital margin, and at the medial border of the orbit a second incision perpendicular to the first, extending about one inch or more. The flap was raised with the raspatory, and the entire upper and medial portions of the orbit, orbital border, and the neighboring parts of the frontal bone were laid bare. The tumor was then exposed, it being in general spherical, with a few flat nodules, which filled the medial half of the orbit, and passing upward and inward to the orbital margin. At the summit of the tumor there was a mass of ivory-like bone, which was sharply defined from the red, spongy, softer surrounding bone, and showing that the tumor was a *hard osteoma incapsuled* by a softer bony shell. Accordingly, this shell was removed piecemeal with the chisel. The shell was in close apposition to the tumor, but it was removed, because it was separated from the tumor by a very thin layer of connective tissue.

The frontal sinus contained considerable pus. The tumor was exposed on its medial border, and a strong iron elevator applied behind it, at the site of the spontaneous perforation. By this means the tumor was forced out of its bed, exposing a prolongation of the tumor, which projected into the nasal fossa. The frontal sinus was found to be very much enlarged, and its lining membrane swelled and congested.

In freeing the tumor a good deal of the enlarged frontal bone, *i.e.*, superior orbital border, was chiselled away, so that under normal conditions the cranial cavity would have been freely laid bare. The wound was carefully disinfected, drained, and an antiseptic dressing applied. Healing without reaction. Ten days after operation the patient was dismissed, with wound closed. During this time the disturbance in circulation of retina disappeared. Movements of eyeball normal, but there was still diplopia. Tumor measured, from above downward, 5.8 ctm.; in greatest diameter from right to left, 3.3 ctm.; in greatest diameter from before backward, 3 ctm.; weight, dried, 50 Gm.

Case XXXII.—Kundrat (*Wiener med. Blätter*, 1883, No. xlviii.) observed an exostosis of the orbit which extended very far into the cranial cavity, therefore it could not (?) be removed. The post-mortem examination showed that the tumor originated from the region of the lamina cribrosa and superior angle of the orbital roof (frontal sinus?). There had been no symptoms of disease of the brain.

Osteoma of the sphenoid.—The only case of osteoma of the sphenoidal sinus in which an attempt was made at removal by an operation, which I have been able to find in literature, is that described by Spencer Watson ("Transactions of the Pathological Society of London," 1868, p. 310, illustration). The patient was a man, aged twenty-one, in whom an osteoma the size of a fist filled the left orbit, displacing the eyeball upward and laterally, but its movements were tolerably perfect, and the sight was very little impaired. Patient had first noticed a swelling at the inner side of the eye, twelve years before, which gradually increased in bulk for six or seven years. Sir William Fergusson removed the tumor, and found that the principal attachment of the deep part of it was to the body of the sphenoid, above the

pterygoid process; there was also a very firm attachment to the upper and inner walls of the orbit. On the third day after the operation the patient became suddenly faint, and rapidly sank.

At the post-mortem examination the brain, with its membranes, was found healthy. Two bony tumors were found lying in the middle and anterior cranial fossæ, the larger of which sprang from the left side of the body of the sphenoid, and was of about the size and shape of a walnut; the other, smaller one was situated at the inner end of the lesser wing of the sphenoid, and immediately above the optic nerve. The optic nerve, although considerably elongated, did not present any other abnormal appearance. The tumor weighed 5,040 grains. Tumor consisted of a superficial ivory-like shell, from one-half to one and a half or two inches thick, and a spongy, vascular nucleus.

Dr. Trimer examined the tumor microscopically, and declared that there was, between the two portions of the tumor, a loose cartilaginous tissue similar to that seen between the epiphyses and shafts of growing bones; but the Committee on Morbid Growths did not confirm this statement respecting the finding of cartilage, and they were of the opinion that the tumor had sprung from the periosteum.

Descriptions of osteomata of the sphenoid have been given by Römhild, J. P. Frank, Pech, and in the *Musée Dupuytren*, No. cccvii., p. 437.

Case I.—*Osteomata of the antrum of Highmore.*—John Howship ("Observations in Surgery and Morbid Anatomy," p. 26, pl. ii., fig. 1). No operation.

Case II.—Manz (Case I., *Archives of Ophthal.*, 1873, vol. viii., p. 321).

Case III.—Hilton ("Guy's Hospital Reports," vol. i., p. 403). In this case the osteoma, originating in the antrum of Highmore, extended into the ethmoidal sinuses. When the patient was a boy, aged thirteen, a swelling showed itself between the orbit and the nasal cavity. After seventeen years the growth became movable; and after it had existed for twenty-three years the skin covering the tumor suppurated, and the latter was spontaneously exfoliated. The cavity which remained was bounded above by the frontal and ethmoidal sinuses, below by the walls of the antrum of Highmore, and inward by the septum of the nose, which was displaced toward the right. Tumor weighed 440 grs.; the greatest diameter was 11 mm.; the smallest, 9 mm.

Case IV.—Duka ("Transactions of Pathological Society of London," 1866, vol. xvii., p. 256, fig. 21, p. 258) removed part of the superior maxillary bone on account of an ivory exostosis of the antrum of Highmore, which had become loose by suppuration. Duka extracted the first bicuspid teeth, and prolonged the incision downward through the upper lip, detached the mucous membrane along the alveolar process, and made a flap. He next removed a triangular piece of bone from the palatine process of the superior maxilla. The tumor was then extracted. The cavity left behind was of great dimensions, the vomer was absorbed, and the right antrum of Highmore had lost its nasal plate. The wound healed by first intention, and the patient left the hospital on the tenth day. The upper part of the tumor lay in contact with the cribriform plate of the ethmoid; at the lower surface of the tumor was a large nipple-like process, which lay in contact with the palatine process. The anterior part of the body of the tumor presented in the nostril. At the base of this process was a large hole, piercing it quite through. In this *lacuna* was a polypoid mass which contained a nucleus of cartilage, round and flat, like a small-sized lentil. The whole bony mass was composed of eburnous structure, weighing 1,060 grains; its long diameter was nearly three inches; the short, one inch and two lines; and the longest circumference, seven inches.

Case V.—Michon ("Mémoires de la Société de Chirurgie de Paris," 1851, tome ii., p. 615). The tumor was so intimately blended with the vomer and maxilla that the whole of the former, and a great part of the latter, came away with it. There was no thin pedicle. The tumor occurred in a man, twenty years of age. The tumor had begun to grow when the patient was sixteen years of age. The growth had developed after a blow, right under the right eye. Eye was displaced upward, outward, and forward, the nose being completely displaced toward left side, and the zygoma laterally. Weight, 122 Gm.; circumference, 15.5 ctm.; height, 6 ctm. It was covered (with the exception of the medial surface) with a soft membrane, the mucous membrane of the antrum. Recovery.

Case VI.—Boyes ("Traité des Maladies Chirurgicales," tome vi., p. 168, Paris, 1818). Exostosis of left maxillary sinus for ten years, which had appeared soon after a venereal infection, which had been followed by secondary symptoms. After having taken one hundred and twenty-eight grains of corrosive sublimate, in less than three months, patient was wholly freed of the exostosis.

Case I.—*Exostoses of the orbit which originate external to the frontal and other pneumatic cavities.*—Stephenson ("Annales d'Oculistique," 1860, p. 21) removed an exostosis from upper border of orbit in a girl aged eighteen. Tumor had developed in three years.

Case II.—Windsor ("Annales d'Oculistique," t. xii., p. 211) removed (with chisel) a bony tumor from the upper and lateral orbital wall, in a woman twenty-four years of age. The tumor projected from the upper border of the orbit and pushed the eyeball downward and forward. It consisted partly of bone and partly of cartilage (?). Had grown in fifteen months. Recovery.

Case III.—Haynes Walton ("Operative Ophthal. Surgery," p. 319, fig. 100). When a child, patient fell downstairs, injuring the *upper orbital border*, at which place a hard, bony tumor formed. When patient was forty years of age the growth occupied the upper edge of the orbit; had a very broad base, its greatest point of projection being two inches. The upper part of the tumor was covered by the eyebrow, which was considerably displaced upward; the lower part touched the eyeball, displacing it downward and outward, the eyeball protruding about one inch beyond its fellow, thereby nearly destroying vision. Tumor was nodular, hard as stone; the skin over it was movable and traversed by a few blood vessels. Walton sawed off the tumor. Recovery ensued, and the sight was completely restored.

Case IV.—Salzer (London *Lancet*, 1831, vol. i., p. 671). A girl, seventeen years of age, received a blow with a rake, whereby the handle entered the right orbit. About eighteen months after injury, when the wound had been healed for a long time, there appeared a hard, immovable tumor at the upper margin of the orbit, displacing the globe downward and inward, so as to almost touch the left nostril. Sight was not completely destroyed. Four years after the accident, Salzer, after several attempts with the hammer and chisel, then with the trephine, which he applied six times, finally removed the tumor piecemeal. Tumor was attached by a broad base. Dried, the pieces of the tumor weighed two ounces. Recovery. Sight restored.

Case V.—Canton, E. (*Medical Times and Gazette*, 1851, vol. xxiii., p. 494). A bony tumor had grown in the orbit of a woman, between twenty and thirty years of age, to the size of a walnut, in seven months, pushing the eyeball forward and outward. No pain was felt; vision was perfect. The orbital ridge on the right side was increased in thickness, and the tumor, continuous with it, passed downward and deeply backward into the orbit. The tumor was detached from the orbital plate with the chisel. Water dressings were applied, and the patient recovered in a week. The tumor was formed, toward the periphery, of compact bone; within, the bone was spongy.

Case VI.—Törnroth et Ilmoni ("Analecta clinica," t. i., fasc. i., Helsingf., 1851, cited by Bornhaupt: *Archiv f. klin. Chirurgie*, Bd. xxvi., p. 613). Patient, aged fifty, had

suffered for five years with gout, when the upper orbit-border became so much swollen that it projected under the upper lid as an oval tumor, which filled the upper lateral portion of the orbit so completely that it was difficult to introduce a sound between the tumor and the swollen lid. The eye was destroyed. Törnroth removed (with Heine's osteotome) the prominent portion of the tumor, which was covered with a firm, callous periosteum, and consisted externally of compact, internally of a spongy substance. Healing took place three months subsequently, after the remaining portion of the tumor had been thrown off by suppuration.

Case VII.—Weinlechner (*Wiener med. Blätter*, 1883, Nos. xlvi.–xlviii.) operated upon an osteoma of the orbit in a man, fifty-one years of age. The tumor had developed at twenty-six. Eye displaced outward; pronounced exophthalmos; amaurosis. The growth extended into the nasal fossa. In operating, the nasal process of the superior maxilla was removed, and the frontal sinus opened.

Later, polyps and remnants of the osteoma were removed from the nasal fossa. Patient died of erysipelas. Tumor originated in diploë of the orbital roof, measured 24 ctm. in circumference, and weighed 281 grs.

Case VIII.—*Ibid.* Removed with good results an ivory tumor of the orbit, in a girl aged sixteen. Had existed for one year. Twelve centimetres in periphery.

Case IX.—Hulke (*Lancet*, 1882, vol. i., p. 910, from floor of orbit). Patient was a girl, aged four. Considerable exophthalmos, first noticed fourteen months previously. The eyeball was displaced downward. The bony mass was attached to roof of orbit. An exploratory incision showed the mass to consist of very vascular spongy bone connected with the external angular process and orbital plate of the frontal bone. It extended almost to the apex of the orbit, and had not any definite boundary. "As its removal was proved not to be feasible, the wound was closed. Immediate union occurred, and the child was taken home." The further progress of the case is unknown.

Case X.—Birnbacher (*Archives of Ophthal.*, 1883, vol. xiii., p. 404). This was a case of ectopia of the eyeball by osteophytis from roof of orbit, with consecutive pneumatosis of supra-orbital region. Eyeball protruded. Difference in apices of corneæ amounted to about five millimetres. Increase in refraction of diseased eye from $H = \frac{1}{24}$ to $M = \frac{1}{30}$, produced by elongation of optic axis caused by pressure on the globe from above downward by bony ridges. An incision was made under and along the lower border of the brow, commencing at the outer angle of the orbit and reaching nearly over the upper border of the lachrymal sac. Having reached the periosteum in the region of the upper orbital border, it was found to stretch over a pneumatic cavity, forming its floor, and containing two larger ridges and one smaller one, of reddish-gray-colored spongy bone, projecting downward against the eyeball. These ridges had their origin in the mass of fine spongy bone which formed the roof of the orbit. They extended two millimetres into depth of orbit, and formed therein a comb which was covered with the periosteum of the roof of the orbit. The periosteum of the floor of the cavity mentioned contained hard plates of bone. Birnbacher believed that the site of irritation which caused the growth of the osteophytes was an inflammatory, non-suppurative affection of the frontal sinus, affecting sympathetically the periosteum of the frontal bone and the roof of the orbit.

Case XI.—Sands (*Archives of Ophthal.*, 1880, vol. ix., p. 471). Patient was a man aged twenty-two. Three years before the operation he noticed a slight protrusion of the right eye, accompanied with deep-seated orbital pain, headache, and vertigo. The exophthalmos had gradually increased since then, and the right nasal passage had become obstructed with a firm mucous polypus, having no connection with the orbital tumor, but the latter had caused some narrowing of the nasal passage, the sides of which were closely approximated. No positive diagnosis was made, although the coincidence of exophthalmos with nasal obstruction led to the suspicion that the tumor was connected with the antrum. A triangular flap, having its apex near the inner canthus, was reflected so as to expose the interior wall of the antrum. This was cut away sufficiently to admit the finger, when it was ascertained that the cavity was empty. The inferior edge of the orbit was gradually removed until the index-finger could penetrate the orbit deeply enough to feel the morbid growth. The tumor was a hard round body, a little larger than a hazel-nut, attached to the superior maxillary bone, far back in the orbit, close to the spheno-maxillary fissure. It was removed with chisel and elevator. A horse-hair drain was introduced into the wound, which was closed with sutures. Patient did well after the operation, and left the hospital at the end of a fortnight, at which time the wound was healed, except along a narrow fistulous track leading to its deepest part. The exophthalmos had almost entirely disappeared. The tumor consisted of a shell of compact bony tissue, containing a large nucleus of cartilage (?).

[I have had an opportunity of examining the specimen of the tumor in the museum of the New York Hospital, and it is made up of cancellous tissue (not cartilage) with a thin shell of compact tissue covering one side of it.—Author.]

It was formerly customary to designate every bony formation in the orbit which showed itself above the plane of the bone an *exostosis*. Cruveilhier was the first observer to direct attention to the differences between the bony tumors of the orbit. He showed that these growths developed in the interior of the bone in such a manner as to push the peripheric layer of bone before them like a capsule; he therefore called them "*incapsuled* bony growths" (corps osseux enkystés) ("Anatomie Pathologique," J. Cruveilhier, tome iii., p. 871). Subsequently Virchow studied the nature of these tumors, and he showed that the orbital osteomata in general may develop in various ways; a great number of them, he believed, originated in the diploë, and in their further development distended the shell of bone enclosing them, which they gradually broke through. These tumors Virchow called *enostoses*, thus separating this form of osteoma from the class of exostoses.

The situation of these growths in the frontal and ethmoidal sinuses, etc., is readily determined, but the question of the actual starting-point is not so easily answered. Rokitansky has suggested that these osteomata of pneumatic cavities were developed from *enchondromata;* but we shall see by reference to the cases of this disease which I have here collected (representing all the cases which have been carefully recorded in literature), that there is no foundation for this opinion.

Professor Arnold, of Heidelberg (*Virchow's Archiv*, 1873, vol. lvii., p. 159), has suggested that the tumors in question were developed from remnants of fœtal cartilage, giving as the only support for this opinion the manner of development of enchondromata from remains of cartilage in other parts of the body. He assumes that at least a part of the osteomata were originally enchondromata, and adduces the fact that a superficial layer of cartilage has been found covering some of these tumors (Case of John Windsor, *Annales d'Oculistique*, 1884, t. xii., p. 211). Then there is the type of development which refers the origin of these tumors to the *endosteum* (?) by direct production of bone-tissue.

By referring to the cases of *osteoma of the frontal sinuses* which I have collected, it will be seen that in those cases in which a careful history has been preserved, and there are data of the time when the growth was first noticed, the latter was noted to have occurred about the period of puberty; therefore, just about the time when these cavities, which are absent at birth, develop with the greatest energy. But the cases of Demarquay

and Solger and others show that osteomata may, in exceptional cases, form in fully developed frontal sinuses.

In consequence of abnormal development in the segment of the frontal bone bordering on the ethmoid, Arnold states, remnants of cartilage may be the starting-point of the new formation, which is first seen as an enchondroma, and later is changed into an osteoma by total ossification (*Virchow's Archiv*, vol. lvii., p. 161).

Pathological anatomy.—Osteomata of the *frontal sinuses* are, as a rule, hard like ivory and irregular in form, with a partly nodular or mammillated surface, sending out conical processes, with which they fasten themselves in the different cavities into which they grow; a fact of great importance to remember in connection with the operation for their removal. Shallow furrows and holes are frequently found in the surface for the reception of blood-vessels and invaginations of the periosteum; or, as noted in two of the cases which we have cited, the grooves in the surface have resulted from the tumor having, while growing, met with resistance from normal osseous projections, ledges, tendons, etc.

The external form of osteomata of the frontal sinuses seems to be essentially influenced by the resisting bodies against which they impinge in growing; and as these are pretty much the same in all cases, it is not curious that these tumors should bear a striking resemblance to one another. We generally find the *largest portion* of the growth in the *frontal sinus*, and a small projection from it in the orbit.

On close inspection, it will be seen that the osteomata of the frontal sinuses consist of two different substances —a thick, ivory-like shell, which generally preponderates, and a spongy portion; the consistence of the former exceeding, in point of hardness, normal compact bone. The spongy portion consists of a system of delicate bony plates, with soft, vascularized tissue between them. When the tumor is cut open, its cut surface displays concentric and radial lines in the ivory substance. The tumor adheres to the frontal bone either by a small pedicle or a broad base of spongy bone.

FIG. 11.—Dolbeau's Case of Osteoma of Frontal Sinus.

Dolbeau maintained, on the basis of pathologico-anatomical investigations and on observations, that the osteomata (exostoses) of the frontal sinus always sprang from the mucous membrane and never from the osseous substance of the wall of the frontal sinus, and that, consequently, by a free opening of the frontal sinus they might be extirpated, just as a stone is removed from the bladder in lithotomy (see Fig. 11). This statement is certainly *incorrect*, as is shown by my own case, and those of others which have been accurately described.

The published cases of osteomata of the frontal sinuses show that the consistence of these growths differs according to preponderance of the spongy or the ivory substance. Generally the ivory-like shell preponderates, and there may be only a trace of spongy bone; then, again, in rare cases, the tumor may consist chiefly of a spongy mass, on which ivory-bone plates are scattered, making the entire growth softer than normal bone. In the majority of the cases which were carefully observed, the entire surface was covered with a delicate connective-tissue envelope; in some instances, parts of this envelope were the seat of polypous excrescences, which sprang out of remains of mucous membrane which had atrophied under the pressure to which it had been subjected by the tumor.

All osteomata of the frontal sinuses not alone distend, but perforate, the walls of the sinuses; but they do not show a tendency to coalesce with the walls of bone which they pierce—a fact of great practical importance in connection with the operation for their removal.

The *perforations* take place, most frequently, *outward* through the anterior plate of the frontal bone, and through the roof of the orbit into the orbital cavity. They rarely project into the nasal cavity. The os planum of the ethmoid bone and the lachrymal bone are destroyed in exceptional cases, where the tumor has such a broad base projecting into the ethmoidal cells that the point of origin of the tumor cannot be made out. Perforation through the inner plate of the frontal bone into the cranial cavity is not uncommon, and this may take place, as is shown by Arnold's case, at an early period, when the tumor was not quite as large as a walnut. The cases recorded show that osteomata of the frontal sinuses may be *unilateral* or *bilateral*; but, in the latter case, there may be only one tumor, perforation taking place through the septum, which seems to be the more common. Then there may be several partly pediculated osteomata in one sinus. But that all osteomata do not, as Arnold asserts, originate in the posterior wall of the frontal sinus, is shown by the cases of Banga, Jobert, and Demarquay, in which the growth was implanted into the anterior plate of the frontal bone.

The osteomata of the ethmoidal cells are, as a rule, spherical in shape, with an irregular nodular surface of the same anatomical structure as the osteomata of the frontal sinuses.

Antrum of Highmore and ethmoidal.—The histological relations in the maxillary cavity are analogous to those in the frontal sinuses, and all the hypotheses relating to the development of these tumors can be applied to tumors of the antrum of Highmore. Arnold's embryological investigations might here likewise come into consideration, since also in this locality preformed cartilaginous parts of the primordial skeleton are found.

The osteomata of antrum Highmori develop in the interior of the antrum of the superior maxilla, from one of the walls of this cavity, and they are generally incapsuled. These tumors also show a tendency to become spontaneously detached by suppuration, a peculiarity which seems to be common to incapsuled osteomata. From the few carefully observed cases of osteomata of the antrum Highmori, it appears that they spring from the medial wall, and show a tendency to grow laterally. They are covered with mucous membrane.

The osteomata of the sphenoidal sinus, as a rule, first extend into the cranial cavity.

All orbital osteomata, external or incapsuled, always show the same structure; *i.e.*, they are composed of an ivory-like portion and a spongy portion; and it seems probable that they all spring directly from the periosteum, and as they grow, the spongy portion is formed by resorption of the ivory mass.

Symptoms.—All orbital osteomata grow very slowly, and, when uncomplicated, are generally painless and without inflammatory symptoms.

Frontal sinus.—In osteoma of the frontal sinus, the patient's attention is first attracted to his disease by the presence of a tumor at the *upper inner angle* of the *orbit*. When the disease is *bilateral*, the prominence takes place in the *middle of the forehead*, directly above the *root of the nose*. Sometimes a collection of pus and mucus in the frontal sinuses complicates these tumors. But the formation of polypi and suppuration in the frontal sinuses, which sometimes complicate these tumors, does not, as has been supposed, give rise to the development of the osteoma; but these conditions are, on the contrary, the result of the presence of the tumor, which, by

closing the channel leading to the nasal cavity, gives rise to retention of mucus in the frontal sinuses, and also the mechanical irritation to which the mucous membrane is subjected during the growth of the tumor. An acute suppurative process may be set up in the cavity, and perforation take place through the walls of the sinus; the external plate of frontal bone being, by preference, the seat of perforation, the pus then making its way, generally, at the inner angle of the orbit, or, as has been observed in an exceptional case, at the upper outer angle, and leading in either case to a fistula in the bone. The *eye is displaced forward* and *downward* and a *little outward*. On account of the slow growth of these tumors the *vision* may long remain unimpaired. Conjunctivitis, ciliary neurosis, disturbance of circulation and inflammatory changes in the retina, and ulceration of the cornea, may result from mechanical disturbance of the eyeball; but they grow so slowly that the eye tolerates their presence for a long time, without having its vision materially disturbed thereby. The *inner plate* of the *frontal bone* may be perforated by the tumor, and the latter attain to considerable dimensions without giving rise to any brain-symptoms. Osteomata of the frontal sinus have, after projecting into the ethmoidal cells, extended to the lamina cribrosa, and through it into the cranial cavity, in which case the osteoma appears to arise from the ethmoidal sinus. But it is more common for tumors in this region to perforate the inner wall of the sinus and invade the cranial cavity.

Ethmoidal sinuses.—The osteomata of the ethmoidal are, as a rule, first observed as a hard tumor at the *inner angle of the orbit*, increasing in its growth from within outward, whereby the eyeball is displaced laterally; the upper margin of the orbit is also sometimes forced upward, and the lower margin downward. But this takes place only in those cases in which the orbital portion of the growth has been very large.

Osteomata of the ethmoidal sinuses may intrude into the nasal cavity. Vision may be normal or greatly impaired. Choked disk has been observed in such cases, and ulceration of the cornea may result where the exophthalmos is so pronounced as to interfere with the closing of the eyelids.

External exostoses.—In the ten cases of *external exostosis* cited above, traumatism was the assignable cause of the exostosis in two cases only. The youngest patient was eighteen years of age and the oldest fifty-one years of age. These exostoses spring from the periosteum. They are generally of the same anatomical structure as those of the frontal and ethmoidal sinuses, consisting of an ivory-like shell with a nucleus of spongy bone. These external exostoses grow much more slowly than the osteomata of the frontal and ethmoidal sinuses, nor do they attain to the same enormous dimensions as do the latter.

The external exostoses of the orbit are generally found at the *upper border of the orbit*, although they may occur at any portion of the orbital border, so that it is not always possible to distinguish between these exostoses and those springing from the frontal and ethmoidal sinuses before the operation.

Antrum of Highmore.—The osteomata in this region spring, as we have seen, from the medial wall of the cavity and show a tendency to grow laterally. The tumor therefore first shows itself, as a rule, behind the lower eyelid, and the eyeball is displaced first upward, then forward and outward. The osteomata in this region break through the thin floor of the orbit, and project into the nasal cavity sooner than the osteomata of the frontal or ethmoidal sinuses; so that the nasal passages are disturbed early in the disease. Perforation into the cranial cavity is rare; I find it mentioned only once, in a case in which the tumor had grown to an enormous size. They are rarely bilateral.

Sphenoidal sinuses.—Osteomata in this region affect the sight, by compression of the optic nerve in the canalis opticus, earlier than the osteomata of the other cavities alluded to. This is readily anticipated on account of the proximity of the growths to the optic nerve. Osseous growths in this region show a disposition to intrude into the cranial cavity at an early stage of the disease.

It has been held that the persistent dropping of fluid (cerebro-spinal fluid) from the nostril, associated with atrophy of the optic nerves and other brain-symptoms observed by Priestley Smith, Baxter, Nettleship, Leber, and others, had an intimate connection with polypoid excrescences and the associated inflammatory affection of the ethmoidal and sphenoidal sinuses. Leber, as is well known, refers these symptoms to hydrocephalus internus, which, in complete ossification of the skull, would give rise to symptoms of brain-pressure.

This circumstance is incidentally referred to here because, since the anatomical investigations of Axel Key and Retzius, the presence of one of these symptoms—dropping of cerebro-spinal fluid—in osteoma of the ethmoidal and sphenoidal, or even frontal, sinuses would have a practical and important bearing on the prognosis of the case. Axel Key and Retzius found that the nervi olfactorii are surrounded by lymph-sheaths which communicate with the subdural spaces, and empty freely on the surface of the mucous membrane of the nose—that the subdural and subarachnoidal fluid of the brain may run off by the lymph-channels of the nose. Therefore, the escape of cerebro-spinal fluid (as demonstrated by chemical analysis by Robin and Mehu), in the case recorded by Tillaux, after evulsion of nasal polypi, would be accounted for by assuming an injury to the lamina cribrosa, but which, like those cases of trauma (in which this symptom was present) recorded by Sir James Paget and Bidloo, was not associated with disease of the optic nerve and those symptoms of cerebral pressure, anosmia, motor weakness, and convulsions which Leber has explained to be due to hydrocephalus internus, giving rise, by pressure, to a small dehiscence in the wall of the ethmoidal or sphenoidal sinuses, and thus to the escape of cerebro-spinal fluid. So long as the tumor is within the limits of the sphenoidal sinus, there may be no subjective symptoms. As the growth increases in size, it enlarges the sinus, and occasions atrophy of its walls, and compresses the optic nerve and the neighboring parts. One or both optic nerves may be affected, and amaurosis result. When the tumor breaks through the walls of the sphenoidal sinus, it extends into the nasal fossa, ethmoidal sinus, and into the orbit, or cranial cavity; and the latter may take place without giving rise to any subjective symptoms. In a later stage, epileptiform seizures may take place. Death generally results from meningitis or brain-abscess.

Diagnosis.—The condition with which osteoma of the frontal and ethmoidal sinuses is most likely to be confounded is a sarcoma with bony spicula or a collection of fluid in these cavities, in consequence of which the sinuses become distended and give rise to a prominence at the place in the orbit at which osteomata of the sinuses in question first show themselves. These retention-tumors are not stone hard like the incapsuled osteomata, but yield to pressure. It is, however, not always possible to make the distinction before exposing the growth by an operation. The drill is of value in making the differential diagnosis in such cases. But when we have these inflammatory conditions as complications of the osteoma, it is not possible to make a distinction. It is, however, of great practical importance to distinguish between the exostoses originating within the orbit and the osteomata of the frontal and ethmoidal sinuses. The exostoses of the orbit, as we have said, may occur at any part of the orbital border, but they have been observed most frequently at the upper margin of the orbit, and they grow much more slowly than the osteomata in either the frontal or ethmoidal cavities. But, after all, a positive diagnosis is only generally made at the operation.

Multiple hyperostoses and diffuse bony prominences

occur in the orbit, which are distributed over a considerable extent of the bone, in connection with some of which constitutional syphilis plays a significant part.

Prognosis.—Spontaneous exfoliation of osteomata of the *ethmoidal sinuses* has been observed in several cases, but the resultant deformity has been frightful. This spontaneous exfoliation has been the result of trauma in most of the cases recorded. Spontaneous exfoliation of osteomata of the frontal sinuses has also been observed in four cases; but this is rare, and the danger to life is far greater in osteomata of the frontal sinuses than in those of the ethmoidal sinuses, on account of the proximity of the latter to the brain and their tendency to perforate the walls of the sinus and extend into the cranial cavity. We can only hope to successfully remove these osteomata by surgical operation. Berger and Tyrmann show that of nine cases collected by them of osteomata of the frontal sinus, which projected into the ethmoidal cells, and in which an operation for their removal was performed, six (66⅔ per cent.) died from meningitis. When an osteoma of the frontal sinus has invaded the ethmoidal sinuses, it has, probably, also perforated the cranial cavity. The operations which I have seen performed on the cranium by general surgeons have convinced me that the prognosis need not be so unfavorable in the latter class of cases, when the operation is performed with care and under antiseptic precautions.

Sphenoidal sinus.—Osteomata in this region generally first extend into the cranial cavity. No case of successful removal of an osteoma from this sinus has been recorded.

Antrum Highmori.—The prognosis after removal of osteomata from this cavity is good, the operative removal of osteomata from this cavity having been favorable in nearly all of the cases recorded.

Berlin states that thirty-eight per cent. of the cases collected by him of osteoma of the orbit which had been operated upon were fatal. This statement applied to osteomata of the orbit in general; but I believe that we should distinguish in such statistics between the regions involved by the osteoma. For instance, Bornhaupt collected 11 operated cases of osteomata of frontal sinus, of which number 7 died of meningitis (sixty-three per cent.), 2 recovered, and of 2 cases the result was unknown.

But the majority of the cases from which these statistics were collected were examples of osteomata which had grown to large dimensions, and had already produced great destruction of the walls of the cavities into which they intruded—in some instances projecting into the cranial cavity—and, as in Tweedy's case, giving rise to degenerative changes in the brain itself. It is unfair to make such cases represent the actual danger of orbital osteomata.

Treatment.—You will observe, by referring to the cases which I have collected, that in osteomata of the frontal and ethmoidal sinuses, etc., we have to deal with a disease which offers the best chances for successful removal when the operation is undertaken at an early period of its existence, before a diseased condition of the tissues (especially suppurative) surrounding the growth has set in; and the latter condition must always constitute an element of great danger in connection with the operation.

There is another reason for operating just so soon as a diagnosis can be made, especially in the case of osteoma of the frontal sinus; *i.e.*, no matter how small the orbital portion of the tumor may be, it is impossible by the orbital portion alone to judge of the real size and extent of an exostosis springing from the frontal sinus. This fact is strikingly shown by Tweedy's case ("Oph. Hosp. Reports," 1882, vol. x., p. 303). The orbital portion of the tumor may be the size of a pea, and yet the entire sinus be filled with the body of the growth.

In our efforts to remove an osteoma from the frontal sinus, it is, I believe, *always better to break down the wall of the cavity through which it has made its passage into the orbit than to make an attempt to remove the growth from the cavity by attacking the body of the growth itself*, since the latter is so hard that a chisel can be forced into it only by employing an unnecessary and harmful amount of violence. It is always reprehensible practice to attempt the removal of an osteoma by attacking it at its apex. The mallet and chisel are, I believe, the best instruments to employ in the removal of these growths.

In every instance the operation should be performed under antiseptic precautions, and after the removal of the osteoma the sinus should be thoroughly searched for polypi which may spring from the lining membrane of the cavity, and when found they should be carefully removed, and the cavity washed with an antiseptic fluid and the wound covered with an antiseptic dressing.

40 WEST TWENTY-FOURTH STREET.

COCAINE AND ITS FASCINATIONS, FROM A PERSONAL EXPERIENCE.

BY FRANK W. RING, A.M., M.D.,

FELLOW OF THE ACADEMY OF MEDICINE, ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, CLINICAL ASSISTANT VANDERBILT CLINIC, ETC.

"To some persons nothing is more fascinating than indulgence in cocaine. It relieves the sense of exhaustion, dispels mental depression, and produces a delicious sense of exhilaration and well-being. The after-effects are at first slight, almost imperceptible, but continual indulgence finally creates a craving which must be satisfied; the individual then becomes nervous, tremulous, sleepless, without appetite, and he is at last reduced to a condition of pitiable neurasthenia."—Editorial in THE MEDICAL RECORD, November 28, 1885.

"Once a man flies to cocaine for relief from 'cares that annoy,' he generally continues with such rapid strides toward such complete subjugation to its bewitching thraldom as but few will ever be rescued from by any power of will which they may be able to bring to their aid."—DR. A. B. SHAW, St. Louis.

"It is not only an antidote to opium poisoning—or, more properly speaking, the organic demand for such drug effects as have been acquired by use—but is itself a fascinating and dangerous intoxicant, the effects of which may be more difficult to counteract and renounce than are those of opium or its derivatives."—DR. ORPHEUS EVERTS, Cincinnati.

"It is a remedy to be used with extreme caution and prudence internally, and the large doses reported as having been given are not ordinarily safe. It will bear watching. It crazes and kills quicker than opium. The possibilities for immediate harm are not only great, but the likelihood of remote damage when tolerance is established is not small. The cocaine habit, more pernicious than the morphine neurosis, is the certain entailment of its frequent administration, and its thraldom is far more tyrannical than the slavery of opium."—DR. CHARLES H. HUGHES, St. Louis.

"I think it for many—notably the large and enlarging number of opium and alcohol *habitués*—the most fascinating and seductive, dangerous and destructive drug extant; and, while admitting its great value in various disordered conditions, earnestly warn all against its careless giving in these cases, and especially insist on the great danger of self-injecting, a course almost certain to entail added ill. And the need of caution against free and frequent using obtains in other cases, for there may come a demand for continued taking that will not be denied."—DR. J. B. MATTISON, Brooklyn.

"I regard the cocaine habit as similar to the tea or coffee habit, and unlike the opium habit. I do not believe there is a single instance of well-pronounced cocaine habit, the patient being unable to stop it at any time if he chose to do so."—DR. W. A. HAMMOND, New York Neurological Society, November 2, 1886 (MEDICAL RECORD Report).

One would judge, from reading the above quotations, that there was quite a difference of opinion in the minds of the medical fraternity in regard to the continued use of cocaine. Such is undoubtedly the fact. It is on account of this widespread discrepancy of belief that I am led to give my personal experience of the drug.

The remarks made by Dr. W. A. Hammond at a meeting of the New York Neurological Society, and a paper published by Dr. J. B. Mattison, "Cocaine Dosage and Cocaine Addiction," subsequently, caused considerable controversy and argument as to whether cocaine was a harmless or a dangerous drug—harmless in large doses, harmless from constant addiction; dangerous in large doses, dangerous from constant addiction—some maintaining that a great and useful drug was being maligned, others giving due credit to its usefulness, and insisting that it should be used with extreme caution.

There are certainly enough well-authenticated cases to satisfy any unbiassed mind as to its danger in large doses. It has killed. It has produced alarming symptoms in numerous instances. The question as to its ability to create a *cocaine habit*, pernicious *per se*, is open to discussion.

I propose to narrate, in as plain and concise a manner as possible, a ten months' constant use of the hydrochlorate of cocaine, taken entirely from an atomizer, and always through the nasal passages.

I have suffered for the past four winters with a chronic follicular pharyngitis, having an hypertrophy of the turbinated bones. Constant closure at night of the nasal passages; I would awaken several times with a dry, parched throat and mouth. Having used the cocaine spray on several patients with marked temporary relief for the same affliction, it occurred to me that an application of it would be beneficial to myself.

About September 1, 1886, I began to use every night, previous to retiring, a spray of a four per cent. solution of cocaine, forcing it into my nostrils by means of a small ball atomizer. For a month, each night, I used about a drachm (two grains).

After the first few applications the relief experienced was well marked. I would go immediately to sleep, and breathe quietly all night long. It was a soporific; a dilator of the nasal passages; in fact, a vehicle to "nature's sweet restorer."

At the end of about four weeks' use I experienced a change gradually coming on. My constant evening spray began to lose one of its principal virtues. Instead of going to sleep immediately, a sense of wakefulness possessed me, and it would be half an hour or more before slumber and rest came on. However, as it had not lost the virtue for which I began its use, I did not mind an hour's fanciful and visionary wakefulness.

During the months of November and December nothing of note occurred. Thinking a less quantity would suffice for the purpose for which I used it, I reduced the dose to about one and a half grains. The period of wakefulness increased, but my sleep was quiet and undisturbed during the night. In January I began to rather enjoy its effects, and to take a spray in the early evening, increasing it to two and three applications, until a member of the family suggested that I would better be careful and not resort to the drug too often. Up to this time I had deceived no one in regard to my use of it. I had informed all my friends, especially of the medical profession, how much relief I got from cocaine, and how often I took it, and how long I had taken it.

It did not occur to me up to within four weeks of its discontinuance that I was becoming dangerously attached to the drug, and in February I stopped it entirely for ten days, just to convince my family that there was absolutely no danger of my becoming a cocaine *habitué*. But I found my breathing was less agreeable and I renewed the employment of it. Through the months of March and April I experienced no ill-effects, unless one may consider two or three hours' inability to sleep as deleterious; but I began to notice a diminution of appetite, which did not disturb me, as that had often happened during the past few years.

On May 1st an incident occurred which saddened my existence to a great extent. I became very much depressed, despondent, and filled with grief. Everything was done mechanically, with lack of interest. Here is where the charms of the cocaine give relief. Temporary relief, but relief. I used it every night four or five times before retiring, each time followed by one or two cigarettes. My nights were passed in a dreamy restlessness, my mind set at ease, and spirits exhilarated. The appetite still decreased, the nerves became unsteady, and I was advised to stop cigarette smoking, which I did entirely for three weeks. About this time I very unwisely began to indulge in an occasional spray at the office during the daytime, something which had never occurred before, and June 27th the climax began. During the fortnight following I had one or two patients "go wrong," suffered from anxiety, worry, and overwork, made four or five visits a day for a week to a person afflicted with a purulent ophthalmia, and after each visit I would turn on forty or fifty pounds pressure, and reduce the liquid in the tube half an inch. Then seeking an easy-chair, with a cigarette in my mouth, I would dwell on the trials and tribulations of this life with a calmness and complacency hardly imaginable. My mind was at rest in less than five minutes, a sensation of exquisite *numbness* would steal over my body, creeping up from the feet to the head, everything looked bright and happy, my grief and anxiety were gone, my troubles were ended. After about a week of this state of things I became somewhat alarmed. My friends could not account for my listlessness, loss of interest in themselves and their pursuits. I assured them it was the result of a little too much cocaine; and after making a feeble effort at facetiousness, would relapse into a condition of silence again.

I did my work mechanically and well; my mind was as level as ever half an hour after these inspirations. At the end of fifteen minutes I would have an inordinate desire to go to the bath-room, and upon rising would find myself staggering a little. I had no desire to talk, but thought I might write a few articles to the medical journals, and I did write, and afterward found that my productions were creditable to a man of ordinary talent. During these *séances* I noted a slight increase in temperature, acceleration of the heart's action, no nausea, no perspiration, mind seemingly clear and active. The numbness only lasted two or three minutes. Thirty minutes after a spray of a solution containing four grains I would be entirely myself again, with the exception of a slight headache, which soon passed away upon using a little bromo-caffeine. I had no appetite during this fortnight of partial bliss, did not sleep well, and lost five pounds of flesh. Probably, during this time I averaged ten grains a day. This is certainly not excessive and would not have caused as much disturbance had I not been under its influence for so long a time. I am sure the second week was more fascinating than the first, and yet I took less cocaine, plainly showing that its effects were cumulative.

July 9th I came to the conclusion that the medicine was getting to be a necessity, that it might become a source of injury to my well-being, and I calmly decided to stop it, which I did. The inclination for it often seizes me, but I crush it with a perfect confidence that I shall never again indulge in its enchantments.

I have computed, from my account with the druggists and recollections of the amount taken, that the cocaine consumed during the ten months will aggregate more than six hundred grains. After the first few months I found a two per cent. solution answered my purpose just as well, and reduced the spray accordingly. Another conclusion arrived at from my experience, not heretofore mentioned, is the fact that cocaine must be ranked among the anaphrodisiacs.

I would not like to have my narration considered as a *confession*, nor as the relation of a series of experimental observations. I used the drug simply as a remedy. Whether it became a pernicious habit I leave others to judge. I would not be willing to take the responsibility of a like continuance with any patient; neither would I put it in the hands of one to be used at his discretion. Several times have I been asked, after spraying the nose, what that medicine was which produced such a marked relief in breathing. The answer is always: a solution of the erythroxylon plant. The words coca and cocaine are not in my vocabulary when addressing patients.

Dr. W. A. Hammond took thirty-eight grains hypodermatically within ten days, the last being a solution of eighteen grains. He got to bed, but how he got there he did not know. His office was in more or less disorder. His head ached for two days, his heart-beats were greatly increased. He experienced no disposition to murder, or to do violent acts. And yet he could not recall what he did during the time that he was under the influence of the drug. Dr. Hammond incurred the danger of six, eight, and eighteen grain-doses for the purpose of ascertaining if there was any truth in the statements in the newspapers regarding the injurious effects of cocaine addiction. He did not acquire the habit. I should have been very much surprised if he had. It is remarkable that he did not acquire a disgust for it. I have saturated my system with crude opium for four or five days, until the formication, loss of sleep, and constipation nearly drove me frantic, and yet I acquired no opium habit. Pernicious habits are not acquired in ten days. Time does the business. Neither are they formed in men of strong and determined wills—men like Dr. Hammond, who have not the time to devote to such fanciful and illusory moments. But, take a man who is ill, downhearted, unable to work, and subject him to my experience, and what would become of him? Would he not be in imminent danger of becoming a cocaine *habitué?*

At the time I began the use of cocaine I was occasionally treated by Dr. W. A. Dayton, Assistant Surgeon to the Manhattan Eye and Ear Hospital. It may be interesting to laryngologists to know the condition of the parts before and after the treatment. Dr. Dayton has kindly handed me the following:

"September, 1886.—The septum naris, unevenly hollowed on the left, with a corresponding bulging on the right side, was eroded at several points from acrid secretion. The mucous membrane of the left turbinated bone was hypertrophic, while that of the right nostril maintained a close approximation to the septum. The posterior extremity of both bodies were enlarged.

"The vault of the pharynx was the seat of considerable thickening, sufficient to partially occlude the mouths of the Eustachian tubes, as manifested by a decrease in the hearing power and the advent of tinnitus aurium. The back wall of the pharynx showed the usual extension of inflammation from the parts above.

"July 28, 1887—Rhinoscopic examination at this time shows: (1) That the breathing space in both nostrils is greatly increased; (2) that the mucous lining of both nostrils is in a comparatively healthy condition, and that the secretion is diminished; (3) that the face of the pharynx from the vault to the base of the tongue is still thickened and swollen, and (4) that the atresia naris formerly existing is certain to recur unless the applications of cocaine are continued or other suitable means be presently adopted to forestall the event."

101 Park Avenue.

Treatment of a Stye.—M. Abadil recommends a three per cent. solution of boracic acid for styes. With a wetted piece of wadding some of this solution is to be dropped on the stye several times a day. It is said not only to effect a cure, but to prevent a return of the annoyance.—*Canada Medical Record.*

Progress of Medical Science.

Pilocarpine in Puerperal Eclampsia.—At a recent meeting of an Australian medical society (*The British Medical Journal*, July 16, 1887), Dr. Finniss related a case of puerperal eclampsia in a woman, aged twenty-four, treated by hypodermic injections of nitrate of pilocarpine. The first seizure occurred twenty-one hours after delivery; the fit was preceded by severe headache. Resort was at first had to chloral and bromide of potassium, combined with the administration of ether during the epileptiform fits, but without much benefit. The first dose of nitrate of pilocarpine (one-fifth of a grain) was administered hypodermatically at 7 A.M., thirty-seven hours after delivery. Within a minute or two profuse perspiration came on, and saliva poured out of her mouth; the pupils contracted a little. She had five more convulsions, with stertorous breathing in the intervals, up to 8 A.M., when the dose was repeated. She had had three more convulsions up to 9 P.M., but these were milder and shorter. During each fit ether was administered to assist in lessening arterial tension. She had no other fit until 2 P.M.; she had another at 2.30 P.M., and a very severe one soon after 3 P.M. Nitrate of pilocarpine, one-third of a grain, was injected; it produced the same physiological action as in the morning. At 8 P.M. she had slept for three hours; the temperature was 104.2°; she was still unconscious; she passed urine and her motions in bed, but had had no more convulsions since the third injection. At 7 A.M. the next morning her temperature was 103°; she had had no return of the convulsions, and had slept at intervals through the night, but was still unconscious. At 8 P.M. of the same day the temperature was 98.2°; she had had a good calm sleep for three hours in the afternoon. She subsequently progressed favorably. There was a trace of albumen in the urine when it was examined on the second day. Mr. Giles stated that he had seen nitrate of pilocarpine used in the Edinburgh Maternity Hospital by Dr. Halliday Croom, in a case of puerperal eclampsia. The convulsions had commenced soon after the birth of the child, the patient being perfectly unconscious, and the breathing stertorous. On the morning of the third day injections, hypodermatically, of one-sixth of a grain of nitrate of pilocarpine were employed, with rapid and very satisfactory effect. In one case he had treated, the convulsion which came on after labor yielded rapidly to injections of nitrate of pilocarpine (one-sixth of a grain) used every two hours for one day. In this case the patient was unconscious about forty-eight hours, and the injections were commenced on the second day. The physiological action of the drug was rapidly produced. Within a minute after the injection drops of perspiration were running off her forehead, which previously was quite dry. After the first injection the frequency of the convulsions diminished, and by evening consciousness returned.

Hypersecretion of Luschka's Tonsil.—Dr. Luc has been led to the following conclusions regarding the hypersecretion of Luschka's tonsil: 1. Whenever chronic pharyngitis, characterized by dryness of the pharyngeal mucous membrane and by scabs and mucous patches on its surface, is present, catarrh of Luschka's tonsil may be diagnosed. 2. Thorough cauterization of the pharyngeal follicles checks catarrh in this cavity, and subsequently cures the secondary pharyngitis. 3. Concomitant symptoms of true ozæna do not contra-indicate direct treatment of Luschka's tonsil. If the complete destruction of this gland does not modify the faulty conformation of the nasal cavities, it often checks the pharyngeal and nasal catarrh, and diminishes the secretion which tends to accumulate in the two cavities. 4. Except in peculiar cases, posterior rhinoscopy, with the help of Voltolini's hook, is preferable to the old method, in cases where the examination of the pharynx and of the pharyngeal vault is required.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 3, 1887.

THE BLUE COLOR OF THE VAGINA AS A DIAGNOSTIC SIGN OF PREGNANCY.

It is a satisfaction to chronicle observations which settle definitely some mooted point in medicine. Certain recent contributions to the *Boston Medical and Surgical Journal* by Dr. John W. Farlow and Dr. J. R. Chadwick belong to this class. Dr. Farlow gives an analysis of 141 cases of pregnancy, with reference to the blue color of the vagina. He tabulates his observations as follows:

Table of 141 *Cases of Pregnancy.*

How long pregnant.	No blue color.	Suggestive.	Characteristic.	Total.
weeks	1	1	..	2
months	11	10	1	22
½ "	5	3	..	8
"	12	5	11	28
½ "	1	1	1	3
"	1	8	10	19
½ "	3	4	7	14
"	..	1	15	16
½ "	..	1	4	5
"	1	..	11	12
½ "	..	..	1	1
"	1	..	3	4
"	..	1	6	7
Total	36	35	70	141

Dr. J. R. Chadwick's tables include observations on 281 cases of pregnant, and 56 of non-pregnant women.

Of the 281 pregnant women, the color was practically absent:

At the end of 2 months in 51 per cent. of the cases.
" " 2½ " 31 " "
" " 3 " 17 " "
" " 3½ " 8 " "
" " 4 " 8 " "
" " 4½ " 9 " "
" " 5 " 4 " "

The color was *suggestive* of pregnancy:

At the end of 2 months in 34 per cent. of the cases.
" " 2½ " 41 " "
" " 3 " 27 " "
" " 3½ " 45 " "
" " 4 " 30 " "
" " 4½ " 4 " "
" " 5 " 20 " "
" " 5½ " 30 " "

The color was *diagnostic*:

At the end of 2 months in 13 per cent. of the cases.
" " 2½ " 28 " "
" " 3 " 46 " "
" " 3½ " 38 " "
" " 4 " 63 " "
" " 4½ " 86 " "
" " 5 " 72 " "
" " 5½ " 70 " "

After (and including) the end of the sixth month, the color was *diagnostic* in all but one case, in which it was *suggestive*, and one in which it was *doubtful*.

This coloration of the vaginal wall, though spoken of as blue, is more nearly a wine-color or violet, and is noted especially upon the anterior wall of the vagina.

With regard to non-pregnant women Dr. Farlow states that among 2,000 gynecological cases he found the blue color quite characteristic in one, and almost characteristic in three, non-pregnant women. Dr. Chadwick gives the following tabulated observations of 56 women who believed themselves pregnant, but were not so:

Table of 56 *Women who proved not to be Pregnant.*

Period after menstruation.	Valueless.		Diagnostic.			Total.
	No color.	Doubtful color.	Suggestive color.	Characteristic color.	General deep color.	
1 week	1	..	1	..	..	2
2 weeks	2	..	..	..	..	2
3 "	2	..	..	..	..	2
4 "	5	3	..	..	1	9
5 "	3	2	1	..	..	6
6 "	12	1	..	..	..	13
7 "	1	..	..	..	..	1
2 months	6	..	..	..	..	6
2½ "	2	1	..	..	..	3
3 "	4	..	..	..	..	4
4 "	1	2	.	..	..	3
5 "	3	..	1	..	..	4
6 "	1	..	..	..	..	1
Total	43	9	3	..	1	56

From this it will be seen that the color was suggestive in three cases and somewhat characteristic in one. The reader can draw his own conclusions from the above data. It is evident that the blue color is not an infallible sign of pregnancy, nor does its absence always exclude pregnancy. Dr. Chadwick, however, seems justified in his opinion that from and including the second month the color is generally present, and often of such a character as to be diagnostic.

From the tables it appears that the color is present at the end of two months in just one-half the cases, at the end of three months in about two-thirds of the cases. After this date the question of its presence or absence is of no very great practical importance, although Dr. Chadwick claims to have found it of assistance in cases of retroversion of the pregnant uterus; extra-uterine pregnancy; in pregnancy complicated with fibroid tumors of the uterus or with ovarian tumors; in pregnancy occurring in women with very fat or tense abdominal walls; when the existence of pregnancy was unknown or concealed; when menstruation persisted after conception; and when conception has occurred during lactation without the intervention of menstruation.

ALCOHOL MORTALITY.

SOME ten years ago a brief report was made to the American Public Health Association regarding the relative mortality of alcohol drinkers and of abstainers. The records of an English life insurance company were taken as the basis of the article. This company began its work with insuring the lives of total abstainers only. But they could not find enough of this class to support the organization, therefore they added to their list moderate drinkers. Separate records were kept of the two classes, and it was found that the average duration of life of the two did not differ except in a very small fraction of a per cent. As these records were kept for some thirty years, they would seem to establish the fact that in England moderate drinking does not shorten life.

On the other hand, another assurance company of London which deals with total abstainers as one class, and all others whose lives are worth insuring as another class, publishes statistics which are decidedly favorable to the total abstainers. Thus, in its last report it states that expected claims in the temperance section are 271; actual claims, 171. In the general section 354 claims were expected, while the actual claims were 331. This would seem to show that about one-sixth more die in the general section than among the total abstainers. There are, we believe, more sources of error in these statistics than in those of the company to which we first referred. Still it can hardly be doubted that a hundred total abstainers of average health have a better chance of life than a hundred moderate drinkers of equally good physique. All that can be said is that a large per cent. of persons can drink moderately without thereby shortening their lives.

THE GAIT OF A CRIMINAL.

A CURIOUS study has been made by Dr. Peracchia of the differences between criminals and law-abiding citizens as exhibited by their walk (*La Riforma Medica*, No. 147, 1887). The author first made a number of observations to determine the conditions of normal progression, and found that in good people the right pace is longer than the left, the lateral separation of the right foot from the median line is less than that of the left, and the angle of deviation of the axis of the foot from a straight line is greater on the right side than on the left.

Comparing these results with those obtained from the study of forty criminals, he found that in the latter the pace was shorter than the normal, a fact which did not seem to coincide with the greater robustness or "toughness" of these individuals. The left pace was longer than the right, the lateral deviation of the right foot was greater than that of the left, and the angle formed by the axis of the foot with the straight line was greater on the left side than on the right. It would thus seem that, in general, the gait of a criminal betrays a marked preponderance of power of the left foot over the right—a true sinistrality. This also agrees with the discovery of Marro that criminals are often left-handed. The moral is, of course, to beware of a left-handed individual, for there is a possibility that he may not be of good moral character.

But this is not all. Dr. Peracchia has not only shown us how we may distinguish criminals in general, but has laid the beginnings of the differential diagnosis between various sorts of evil-doers. The following are the distinguishing characteristics which his observations have enabled him to formulate:

1. *Thieves.*—In those who are predisposed to appropriate the property of others there is a pronounced widening of the base of support, together with a very long step.

2. *Assassins.*—In those who have murder in their hearts the base of support is not as wide as it is in thieves, since the angle formed by the axis of the foot with the median straight line is less obtuse, but the sinistrality betrayed by their foot-prints is very marked.

3. *Ravishers.*—Those whose tendencies are in the direction of rape may possibly be detected by a skilled diagnostician by the fact that they take short steps and have no sinistrality to speak of.

These discoveries are of a very interesting character, and if the criminal could be induced to walk before the honest man, instead of following him as he usually does, they might also be put to a practical use, for then good citizens could diagnose the rogue by his tracks, and might thus be enabled to escape robbery, assassination, or rape, as the case might be.

REQUIRING PRELIMINARY EXAMINATION.

WE are glad to find that the College of Physicians and Surgeons of this city proposes next year to require preliminary education of its matriculants. Applicants who do not bring evidence, in the shape of degrees or certificates, of a satisfactory general education, will have to be examined in English composition, Latin, arithmetic, algebra, and geometry. The amount of knowledge required on these subjects is very elementary and need deter no one. Experience in other institutions of humbler pretensions, but with less fear perhaps of frightening away pupils, has shown that a knowledge of modern languages can be safely accepted as a substitute for geometry or algebra.

MIXED HOSPITAL BOARDS AND THE MORTALITY-RATE.

THE annual reports of the Cook County Hospital reveal some facts in which the profession should feel some interest. On the opening pages we find a list of the members of the "regular medical board," and below of the "homœopathic medical board." Such juxta-position seems a little at variance with conventional ethics, but in this we may be mistaken.

The point that is of real importance is, that both in its totals and in the medical and surgical departments, the mortality of patients treated by the homœopathic medical board is less than that of the regular board. And this is true not for one year, but apparently for a series of years. For example, in 1884 the mortality on the regular medical side was about $\frac{1}{11}$ of the total treated (406 to 4,692), that on the homœopathic side about $\frac{1}{12}$ (103 to 1,242).

In 1885–86 the figures were for the regular school $\frac{1}{13}$ (448 to 5,909) to $\frac{1}{15}$ (105 to 1,532), and a similar excess of mortality-rate is carried through the medical and surgical departments.

It is possible that the cases sent to the homœopathic side are of the less severe and acute character. Unless some such explanation as this exists, the reproach upon the skill of the regular medical staff is a severe one. Hospital statistics are extremely fallacious things, to be sure, and no inferences should be drawn from them without careful examination. But in the Cook County Hospital such examination seems demanded.

MEDICAL LAWS AND ETHICAL DECADENCE.

THE question whether the enactment of laws for the regulation of medical practice may not tend to lower the ethical tone of the profession has been raised, and it is no doubt a serious one. Some physicians seem to feel that, so long as they are legal doctors and can collect

their bills, they can stay in the ranks with their reputable brethren, no matter how lax they grow in matters of professional dignity and honesty. The editor of the *Pacific Medical and Surgical Journal* says: "Since it has been attempted to regulate the practice of medicine in this State by means of legal enactments, the members of the profession seem to imagine that they are no longer individually responsible for the enforcement of the lines of conduct prescribed in the Code of Medical Ethics; we would, however, seek to remind them that, since everything which is medically legal is not medically ethical, the duty of maintaining the dignity of the profession still remains with them."

It is to be remembered, however, in connection with the above, that the medical laws of California are far from satisfactory. Stricter requirements will exclude a considerable proportion of those who now indulge in the practices referred to.

THE SUPREMACY OF DIGITALIS.

Professor R. Kobert, in an article on the influence of pharmacological agents on peripheral vessels (*Therapeutic Gazette, June*, 1887), discusses the action of digitalis as compared with that of other substances of the same group, viz., convallaria, strophanthus, apocynum, adonine, helleboreine, soillaine, erythrophleine, and barium chloride.

He states that in digitalis there are three active principles—digitalin of Schmiedeberg, digitoxin, and digitalein. Now digitalin has the power, like all the other substances of the digitalis group, of contracting the blood-vessels of the body, but, in marked contrast to all the others, digitoxin and digitalein in ordinary doses do not contract, but dilate, the vessels of the kidney. Hence, we have in digitalis alone a drug which increases the force of the heart-beat and narrows the peripheral circulation, except that of the kidneys. We have, therefore, the ideal diuretic so far as the vascular apparatus goes, for it not only increases the rapidity of the renal circulation, but augments its volume. Dr. Fraser claims this same peculiarity for strophanthine, but Professor Kobert is not yet ready to admit it, and says that "the leaves of digitalis purpurea are an agent which can be supplanted by *none* of the many other vaso-motor remedies, for we are as yet ignorant of other remedies which act like digitoxin and digitalein. The importance," he adds, "of my statement, that digitalis medication has no substitute, every practitioner will admit. The substitution for digitalis of adonis, convallaria, etc., is not because digitalis does not affect the heart properly, but because digitalis often causes vomiting and purging in certain patients in whom the other drugs, adonis, convallaria, strophanthus, etc., do not produce such results."

As to the best preparation, we infer that Professor Kobert recommends the leaves, the tincture, and the alcoholic extract, since alcohol dissolves the three important active principles. In fluid extracts the digitoxin is precipitated as an insoluble powder. When the leaves are imperfectly dried a decomposition sets in which not only destroys the active principles, but may produce new and poisonous compounds. Similar decomposition may occur when the tincture is mixed with watery or syrupy solutions. The practice, said to be prevalent in this country, of not preparing the drug from the leaves when desired, but from a concentrated infusion, is a bad one.

The conclusion is that digitalis still holds and deserves its supremacy as a diuretic and cardiac tonic, but great care is needed in prescribing it. Well-dried, powdered leaves, the extract or the tincture, are the surest preparations. The practitioner should not forget that, although digitalis improves the cardiac rhythm, strengthens the pulse, and lessens dropsy, its general effect upon striped muscle is to lessen the contractive power. In cases in which this muscular weakness and languor are pronounced, barium chloride may be tried, since this drug, though not a heart-tonic directly, yet contracts the blood-vessels and may produce sufficient diuresis, while it does not depress but increases muscular contractility.

Professor Kobert's studies furnish a striking illustration of the practical value of pharmacological study.

News of the Week.

A New Theory of Ice-cream Poisoning.—Dr. George S. Hull, of Chambersburg, Pa., writing in the *Medical Times*, says that electricity is generated by the revolving zinc paddles in ice-cream freezers, the zinc is dissolved, and thus the ice-cream becomes poisonous.

The Death under Ether Anæsthesia of a patient of Dr. Agnew, of Philadelphia, would seem to have been due to shock or apprehension rather than to the toxic effects of ether. The post-mortem examination, made by Dr. Formad, showed evidences of old inflammatory and degenerative lesions in the brain and cord. The lungs were collapsed and not congested.

Prizes for Essays on Hygiene.—The Spanish Society of Hygiene advertises prizes for the best essays on "The Hygiene of Work in Childhood," and "Means of Preventing the Evil Effects on the Eyesight by Faulty Conditions of Schools and of Methods of Instruction." The prizes, of $50 each, are open to universal competition, but the essays must be written in Latin, French, Spanish, Italian, or Portuguese.

The Health of London.—There has been a large increase recently in the number of fever patients treated by the Metropolitan Asylums Board of London, the figures being but little below the highest number reached in fourteen years.

An Ovariotomy Record.—On August 2d, Dr. von Nussbaum performed his five hundredth ovariotomy in Munich, and this was made the occasion of an ovation to the professor by his students, who presented him with a bouquet in which the number 500, probably in flowers of of a bright red hue, stood prominently forth.

Dr. Arányi Hunyadvár, professor of pathological anatomy in the University of Budapest, died recently, in his seventy-ninth year.

American Academy of Medicine.—The annual meeting of the American Academy of Medicine will be held at Columbian College, Washington, Saturday, September 3, at 12 M. The annual dinner will be given at the Arlington Hotel in the evening of the same day.

A Court Physician Beheaded.—The Ameer of Afghanistan suffered not long ago from a boil on his neck and sought relief at the hands of his court physician. The latter ordered some sort of a salve to bring the boil to a head. Unfortunately the application caused the august patient considerable pain, and after a night of torture he sent for his physician and had him decapitated. Evidently the physician to the Ameer does not hold a sinecure.

Paracentesis Extraordinary.—Dr. A. Miceli reports in the *Rivista Clinica e Terapeutica* a case of ascites a frigore, in which paracentesis was performed thirty-four times, at first at intervals of a few days, and then of weeks and months. Finally the fluid ceased to reaccumulate and the patient, a young woman, made a good recovery, married, and became the mother of children.

Feeding by the Rectum for a Long Period.—Dr. A. Longhi reports in the *Gazzetta degli Ospitali* the case of a youth, aged fifteen, who was unable to swallow by reason of some trouble in the œsophagus. He was fed by the rectum for three months, not a particle of food or drink entering his stomach in that time. He suffered neither from hunger nor from thirst, and gained steadily in flesh and strength.

Hebrews in the Russian Universities.—The Russian journals are discussing the question of restricting the number of Jewish students in the universities. In some of the departments their number is insignificant, but in the medical faculties there are 224 Hebrews in every 1,000 students. In the medical department of the University of Kharkoff 41.5 per cent. of the students are of this race. The authorities seem to be alarmed at these figures, and, according to *Vratch*, the Minister of Instruction has ordered that hereafter the number of Jews at this university shall not exceed five per cent. of the whole number of students.

A New Medical Society has been formed in an Illinois town, according to the *Western Medical Reporter*, the only requisite for membership in which is that the applicant shall possess a certificate to practise medicine from the Illinois State Board of Health. Regular physicians and practitioners of all the different "pathies" meet together in seeming concord, and it is even proposed to establish a dispensary to be run by the members of the society.

Delegates to the International Congress.—The foreign delegates to the Congress are beginning to arrive. About forty came on the steamers arriving in New York on Sunday, and others during the week. It is stated that about three hundred and forty physicians from abroad have sent in their names for registration.

A Scientific Exhibition will be connected with the sixtieth congress of German Naturalists and Physicians, to be held in Wiesbaden from September 15 to 24, 1887. Its purpose will be to show at a glance the latest and most perfected instruments and apparatus which have been placed at the disposal of science and medicine in the last few years, and anything that cannot lay claim to be ranked in this category will be rigorously excluded. No charge will be made for space or insertion in the catalogue, and the instruments, while there, will be covered against risk by fire at the expense of the committee. Applications are to be addressed to the Ausstellungs-Committee, Versammlung Deutscher Naturforscher und Aerzte, 44 Frankfurterstrasse, Wiesbaden.

The Library of the Surgeon-General's Office.—The work of transferring the books in the office of the surgeon-general's office from the old quarters in Ford's Theatre, where President Lincoln was assassinated, to the new building on the corner of Seventh and B Streets, is being rapidly carried forward. The new building occupies the space in the southeast corner of the Smithsonian grounds. The front on B Street is 232 feet, the central portion having a frontage of 112 feet. The wings on the east and west side are each 60 feet front, with a depth of 131 feet. The building is of brick, three stories in height, and is fire-proof. The library occupies the west wing, and the army medical museum the east wing. It is hoped that the books will be all arranged on the shelves in the early part of this month.

A Prize Competition.—The *Lancet* states that the Medical Institute of Valencia offers gold medals for the best works on the following topics: 1, Chorea; 2, Ovarian Tumors; 3, The Medicinal Plants of Valencia; 4, any scientific subject, at the option of the author. The essays, which may be written in English, are to be sent to the *Secretario de Gobierno, calle del Triador*, No. 11, by December 1, 1887. The announcement of the results will take place on March 31, 1888. The competition is open to medical men and pharmacists of all nationalities.

Professor Sayre's Danish Disciples.—Dr. Levy, of Copenhagen, has written a letter to Dr. Sayre, in which he states that he has employed the plaster-jacket treatment, which he considers constitutes one of the greatest advances ever made in orthopedic surgery, in thousands of cases, and that it is now generally adopted by his colleagues in Denmark. He also states that they likewise adhere to Dr. Sayre's maxims with regard to the treatment of club-foot in all essential points, and that Danish orthopedics now rests to a large extent on the "conceptions and proposals emanating from Dr. Sayre and his school."—*Gaillard's Medical Journal.*

The Late Dr. Rudolph Mautner.—A special meeting of the Richmond County Medical Society was held at the S. R. Smith Infirmary, Wednesday, August 24, 1887, to take action in regard to the death of the late Dr. Mautner. The committee, Drs. Van Rensselaer, William C. Walser, and O. Dea, offered the following:

Whereas, It has pleased the Almighty, in his infinite wisdom, to remove our co-laborer, Dr. Rudolph Mautner, from his worldly sphere of usefulness; therefore

Resolved, That we hereby record our deep appreciation of the high personal character and professional attainments of our said deceased friend;

Resolved, That we tender our heartfelt sympathy to his bereaved widow and family in their grievous loss and affliction;

Resolved, That a copy of the above preamble and resolutions, be sent to the family of the deceased.

J. Walter Wood, M.D.,
Secretary Richmond County Medical Society.

Reports of Societies.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION IN DUBLIN.

(Special Report to The Medical Record.)

MEDICAL SECTION.

First Day, August 3d.

The Medical Section held its first sitting on August 3d. The President, Dr. William Moore, occupied the Chair, and delivered the inaugural address. He adverted to the advance made in the important question of fevers, as regarded their specific characters, their diagnosis and treatment. In his student days no branch of medicine was more unsatisfactory than the diagnosis and treatment of fevers; and hence we did not know what the future had in store for the medical art in regard to the treatment and prevention of these fatal diseases. We must admit, he said, that many practitioners without scientific pretensions had proved more successful in the treatment of these diseases—a treatment derived from their common sense and experience alone—than many persons of greater scientific attainments. We must as much as possible, he continued, elevate the profession from the condition of a simple art and make it a scientific art. In the meantime experience had revealed many remedies, which we must not discard.

Dr. Charlton Bastian, of London, opened a discussion on

APHASIA.

After referring to the various theories as to the part of the brain affected in aphasia, Dr. Bastian said that he accepted all the facts which related to the phenomena of aphasia, but interpreted them differently from several authors. In his opinion, there were four brain-centres connected with this disease, the visual and auditory centres on the one hand, and two centres of motion, the cheiro-kinetic and the glosso-kinetic. The third left frontal convolution was the situation of the glosso-kinetic centre, while the cheiro-kinetic was situated above this, in the superior frontal convolutions. The auditory and visual centres, again, were situated posterior to these kinetic centres, and probably in time it would become possible to localize their centres. It was not necessary to use the word centre, for probably the activity of the brain was diffused over large areas. In all probability it would be found that there were definite portions of the brain connected with blindness and deafness. A patient might be word-blind, although not blind in other respects, and others might be word-deaf, although not deaf to ordinary sounds. The auditory and visual centres were, he thought, situated at the posterior part of the upper frontal convolution. In ordinary silent thought there was a revival of words in the auditory centres. When speech took place a stimulus must pass along to Broca's convolution. He should call those fibres which connected motor and sensory centres internuncial. All the different forms of defect of speech were, he maintained, explicable by this hypothesis. If there were damage to any of these fibres, some form or other of loss of speech might ensue. His opinion was that there were no motor centres in the cortex. He differed in his hypothesis from Dr. Hughlings Jackson, who thought that words are revived in the glosso-kinetic centre, for there was no proof that this could occur. And that author's view, that there were motor-centres in the cortex, was, he thought, erroneous. Lesions of the bulb are not associated with either loss of memory or paralysis. When *aphemia*, as distinguished from aphasia, occurred, the mind remained unaffected, and the aphemic patient can express his ideas quite well in writing, and his intelligence remain excellent. One patient of his, of this kind, could not speak a word, but could write all he needed to express very clearly, and Dr. Bastian thought that in such a case the internuncial fibres for speech had been affected, leaving the visual and auditory centres intact. Dr. Hughlings Jackson would not grant that such cases existed. In some cases the power of writing alone had been destroyed, and the patient had loss of muscular sense. In the early days of the controversy about aphasia, observers had brought forward cases where Broca's convolution had remained untouched while aphasia occurred. This might be explained by his hypothesis that in such cases the internodial fibres might be affected, and thus the localization hypothesis would not be destroyed in any way. Thus many cases of aphasia had been reported where the Island of Reil had been found to be affected, which could, he contended, be explained by his hypothesis. When the auditory centre was affected then aphasia coincided with word-deafness, and the same held with word-blindness. He had a patient, in 1878, who, if he heard a word pronounced, could say it, and could read and understand the paper, but could not speak a word. He could also copy a word, but if told to do this he could not comply, and could not write from dictation.

In the discussion which ensued on Dr. Bastian's paper, Sir George Paget, of Cambridge, observed that of course it was well known that aphasia usually accompanied right hemiplegia. In left-handed persons, however, this was found not always to be the case, for then the centre of speech was transferred to the right hemisphere. A patient and friend of his, a left-handed man, of very great eloquence, was seized with a slight attack of right hemiplegia and aphasia, and was seen a few hours after the seizure. By that time he could only say the words yes and no. His right side showed paresis of the arm, and ataxia of the leg. The next day the patient could speak, and then got pretty well again. Two years and a half after this, he had another attack, at the same time in the morning as the former, and his wife found him lying insensible on the floor. He was then ataxic and had palsy of the left arm, and loss of sensation in that arm, but he could speak quite well. Three years subsequently he had a tremendous attack of right hemiplegia, and recovered to a certain extent, living for three years after, but remaining speechless till he died. He uttered sounds, but, although he seemed to be talking, the sounds were quite unintelligible. This gentleman had been a most accurate speaker, and used his words with the greatest precision. His only recreation was chess, and he used his left hand for moving the men, but could write well with the right hand as he had been taught to write with that hand. In this case the left hemisphere being used for writing, the same hemisphere was used for speech as usual.

Dr. Gairdner, of Glasgow, thought that when an infant began to speak it gradually made ruts in its brain, which were made use of in future life. This hypothesis was not at all subversive of that of Dr. Bastian, with whose views he was disposed to agree. When the child began to write, it opened out a new rut in the cheiro-kinetic portion of the brain. The case of the late Lord Denman had been mentioned before by himself in the discussion on aphasia which took place at the Worcester meeting. That gentleman was suddenly paralyzed, but as far as his daughter could judge, his intellect remained unaffected. Thus he went on reading works daily in various languages, and was so bent on communicating his ideas to others, that he registered his opinions by making his daughters copy out portions of various books and send them off to his friends, to let them know what he was thinking about. There was, said Dr. Gairdner, a certain amount of aphasia in all persons after a certain period of life. Relatively speaking, all were aphasic. In his own case, there was a certain preparation of digitalis which he could never remember the name of. At last, after numerous attempts to fix it in his mind, he did so by artificial memory. And, in the

same way, there was a gentleman with whom he was acquainted and occasionally visited, and yet, although he had seen him for years, he could not remember the name of his house without an artifice of that kind. All individuals might throw light on this subject if they pleased. A patient of his could not remember any word, and though he was a good player at dominoes, could not remember any of the numbers on the dominoes. Yet he could work with numbers by his hand, although he could not pick up a number if asked to do so. One day this man came to tell him that the number forty-three on his card was wrong, and that it should be thirty-three, and he thus discovered that he could write the Arabic figures quite well, although he could not use verbal signs.

Dr. Nixon, of Dublin, found some difficulty in adopting Dr. Bastian's hypothesis. He mentioned a case of a patient recently seen with right hemiplegia. This patient said he was a Roman Catholic, he was sorry to say, and when remonstrated with by his sister for this remark, he said: "Not at all." The man was nearly speechless, and died in four days, when the post-mortem examination revealed the almost complete occlusion of the Sylvian artery. He held that there were three forms of the disease, (1) aphemia, (2) ataxic aphasia, (3) agraphia. Dr. Jackson's views were that the words must be revived in Broca's convolution, and he thought, after all, that the question came to be one of definition rather than of notable change of opinion between Drs. Jackson and Bastian.

Dr. Banks, president of the meeting, was struck with what Dr. Gairdner had said about Lord Denman. He himself had seen patients with aphasia where the intellect had been quite intact. In one curious case a gentleman with aphasia looked about everywhere for his will, and when he found it, tore it in pieces with his left hand and his teeth. He died shortly afterward, and his will was considered to stand, and the pieces of it were put together and approved of by the judge of the Probate Court. Another very singular case had occurred in a "grinder" of Trinity College, Dublin, who prepared students for examination. He became aphasic, and after being so for some time, he recovered the powers of speech as far as English went, while he entirely forgot Greek and Latin, in which he had been such a proficient. Upon this he began again to study these two languages carefully, and learnt them very rapidly. A lady patient recovered completely from right hemiplegia and aphasia. While she was in the aphasic condition, she could write admirably well. He was strongly of opinion that in many cases of aphasia, the mental condition was quite intact, and he considered this as a very important point in medico-legal cases connected with this symptom.

Dr. Bastian, in reply, said he had listened with great interest to Dr. G. Paget's case, and also to the remarkable case of Lord Denman; that case he considered to be one where there was lesion of the internuncial fibres. With regard to Dr. Gairdner's point, he also was himself getting into the state of partial forgetfulness of certain names. For ordinary cases the auditory centre might be lost, and in such cases the patient would not be able to recall the names of things. In the same way volitional speech will occasionally be lost. Briefly, there were afferent, internuncial, and kinetic fibres, any of which might be interfered with and give a certain series of symptoms of aphasia.

Dr. Murphy read some notes of a case of recurring aphasia in a child, with certain complications, ending in recovery, and this terminated the debate on the general question of aphasia.

A paper was read on

SYPHILITIC APHASIA

by Dr. C. R. Drysdale, of London. The author said he had seen a case of syphilitic aphasia as early as 1861 in Dr. Gubler's ward at the Hôpital Beaujon at Paris. That year Dr. Broca wrote his work on aphemia, a term altered to aphasia by Professor Trousseau. At that time it was not, as now, known that syphilis could cause aphasia by narrowing the calibre of the vessels of the brain, or by the formation of gummy tumors. In all cases of syphilitic aphasia which he had treated there had been right hemiplegia. The first of these he had under his care was that of a gentleman who, in 1851, contracted syphilis. He was a most intellectual man and a celebrated professional. This gentleman had suffered for many years with fits of vertigo, which yielded well to iodide of potassium, and suddenly, in 1871, or twenty years after the initial lesion, he had an attack of right hemiplegia and aphasia. His general health continued pretty good, but the symptoms of complete aphasia and hemiplegia remained quite unaffected by treatment. He died in 1886 after being aphasic for fifteen years. Another distinguished literary man contracted syphilis in 1870, and had symptoms resembling locomotor ataxia three years subsequently, with mental disturbances. In 1876 he was attacked with right hemiplegia and was speechless for a time. Remedies were of great service to him at that date. However, in 1887, being in Ireland on a visit, he was carried off by a cerebral attack. In 1869 a patient was brought to the Metropolitan Free Hospital of London with complete aphasia and right hemiplegia. He was covered with an eruption of syphilitic roseola. Remedies, such as large doses of the iodide of potassium and mercurial inunction, did a little good, but not much, and he left the hospital only to enter one of the workhouse infirmaries of London, apparently in an incurable state. In some cases, doubtless, said Dr. Drysdale, when the brain affection is slight, it may be cured and no relapses take place, but prognosis must be very guarded, for at any moment another cerebral attack may ensue and carry off the patient. In passing he thought a statue should be erected to Dr. Wallace, of Dublin, who was the discoverer of the virtues of iodide of potassium in syphilis. Before his day syphilis was a terrible disease, indeed, but since then, although still formidable, it had been disarmed of many of its most hideous and distressing phenomena.

Dr. Ringwood, County Meath, mentioned the case of a blind man who contracted syphilis, and, after two years, became aphasic. He was a most sad case, since, being blind and dumb, he could not communicate his wants in any way. The word No was all he could utter. The attack of right hemiplegia was transient, and the power of speech returned. When aphasic, the only way he could sign to others persons was by the nurse placing his finger on the raised letters, and when he did not want the letter, he said No. A case was mentioned where the patient had destruction of a great portion of the left frontal convolutions, following on encephalitis of the gray matter.

Dr. Grainger Stewart, of Edinburgh, delivered an address on

ALBUMINURIA,

wherein he showed, from a large number of cases of albuminuria occurring in all sorts of people, that this symptom was compatible with perfect health. He had made a large number of experiments to ascertain under what circumstances albuminuria might be expected to be found in health. In 407 healthy soldiers he found, after breakfast in the forenoon, that 66 gave reactions for albumen with cold nitric acid, and that 63 more, who did not show the albumen with nitric acid, showed it with the picric acid test, *i.e.*, 129 altogether out of the 407, or 31.7 per cent., showed traces of albumen. In passing, he would say that the results of these tests went to show that picric acid was a more delicate test than nitric acid. For instance, when urine diluted fifty times would still show albumen with nitric acid, it would do this with picric acid when diluted one thousand times. In another experiment, he took 205 soldiers, and found traces of albumen in the urine in 37.56 per

cent., whereas in 74 cases of persons in civil life of similar ages to those of the soldiers, the percentage was only 10.8. With regard to the effect of age, he took 40 children, and found the urine of 17.5 of these to contain albumen; whereas that of 40 old persons showed it in 67.5 per cent. In another experiment with various classes, he took patients before and after breakfast, and found that in soldiers there were 15.6 per cent. who had traces of albumen in the urine before breakfast, and 40.6 per cent. after breakfast. In old men the figures were 37.5 before and 67.5 after breakfast; in children, they were 12.5 before and 17.5 after breakfast. Finally, in 46 children in an orphan asylum, 14.6 exhibited traces of albumen before, and 20.03 after breakfast. In another experiment, some soldiers showed 29 per cent. of traces of albumen before a march of eight miles, and 19 per cent after it. But, after fatigue work of coaling in Edinburgh Castle, there were 44 per cent. with albumen in urine before, and 64 after the hard work. This showed that gentle exercise was of service in getting rid of albuminuria, while violent exercise was the reverse. As to cold bathing, the experiment was made on the urine of 21 boys in an orphanage, and 19 per cent. of them exhibited albuminuria before, against 23.8 after cold bathing, which did not show much difference.

In the discussion which followed, Sir A. Clark said he was able to fill up one of the points which Dr. G. Stewart had not been able to do. The Indian Civil Service forced all competitors on its posts to be examined very carefully on this point. He had need to examine a great many of such candidates, and the result was that of those persons who came up in health for examination about 30 per cent. had albumen in their urine, which lasted for two or three months after the examination. His plan of examination was to put a little of a diluted solution of nitric acid on a test-tube, and float over it some urine.

Dr. Drysdale, of London, was quite aware of the frequency with which albumen occurred in the healthy; but there was rather a danger lest many practitioners might begin to give too favorable a prognosis in albuminuria, just as was the case in morbus cordis, because many cases of these diseases were compatible with longevity. Each case must be carefully studied, and the symptoms closely watched, for as yet it was not clearly ascertained what cases would soon carry off the patient by some complication, and what might be disregarded.

Dr. Charles Ralfe, of London, read a paper on

CERTAIN NEPHRALGIAS SIMULATING RENAL CALCULUS.

Many states might simulate all the symptoms of renal calculus. For instance, in one case, a man who was supposed to have calculus in the kidney of the left side, died suddenly one night. It was then found that he died of aneurism of the abdominal aorta. On the other hand, in a case mentioned in a Chicago journal, neuralgia had been diagnosed, but in a short time the man passed an oxalate of lime calculus, and his urine became thick and bloody. True neuralgia of the kidney was very rare. Delicate women might show some symptoms of it, and renal neuralgia might occur in malaria. In another case, a patient died, in 1880, in the London Hospital, who had pain in the region of the kidney. After death no stone was found; but there was hypertrophy of the left ventricle of the heart. Many morbid conditions of the duodenum might simulate calculus in the kidney. In one case where a calculus was suspected, a purge was given, and a round-worm was expelled. Gall-stones had been mistaken for calculus in the kidney of the right side, and caries of the vertebral column had excited symptoms which had been mistaken for it. So, also, had psoas abscess. Prout had described cases of hæmaturia and nephralgia due to functional disease of the urinary organs. In such cases there was constant desire for micturition, colicky pains, etc. Dyspeptic patients had often symptoms which simulated calculus in the kidney.

Dr. Martin, of Portland, mentioned a case where a man who had a cavity in the lung, had also an immense quantity of albumen in his urine. Notwithstanding these grave symptoms, he did a good deal of hard, manual labor. On Monday he would go to his work quite fresh and well, but on Saturday he was entirely exhausted. He continued in this state for a long time, and then was carried off.

Dr. Drysdale, of London, said that Dr. Ralfe's paper showed how careful practitioners should be not to perform nephrectomy unless they were very certain of the existence of a stone. He had seen the operation performed on more than one occasion, and no stone found, and it was too dangerous an operation to trifle with.

Dr. Grainger Stewart observed that the amount of albumen in the urine did not rank highly with him in prognosis. When a patient came with albuminuria, it might sometimes be said, "You may disregard the symptom entirely." The question was a very delicate one in many cases, and required the greatest attention on the part of the adviser. One case had struck him greatly. He was attending a gentleman with albuminuria, when his wife one day said to him, "I have far more albumen in my urine than my husband." Yet she did not trouble to do anything for it. It turned out that this lady had had scarlatina at the age of eight years, and albuminuria, which had continued the whole of her life. Her age was forty-four years at that time. Shortly afterward she died of uræmia. He had stood by when a patient with supposed stone in the kidney had been operated on. When the incision in the kidney was made, and it was injected and no calculus found, he had had a strange feeling. This patient had had bloody urine, with oxalate of lime in it, and retraction of the testes.

Dr. Drummond, of Newcastle-on-Tyne, said that alcoholic excesses might cause albuminuria. In fifteen cases of floating kidney which he had detailed, he had heard from the patient that there was a sensation of heat in the organ. Otherwise it was impossible to localize disease of the kidney in most cases.

The Section then adjourned.

SECOND DAY, AUGUST 4TH.

The first paper of the day was read by Dr. Drummond, of Newcastle-on-Tyne, entitled:

SYMPTOMS SUGGESTIVE OF GENERAL PARALYSIS OF THE INSANE, DEPENDING UPON THE CIRCULATION IN THE BLOOD OF DIGESTIVE IMPURITIES, IN AN INSIDIOUS CASE OF NON-ALCOHOLIC CIRRHOSIS.

A man for eighteen years had been exposed to malarial influences. In 1886 he complained of dyspepsia, and began to walk about the streets aimlessly. He was a sailor. In 1866 he was admitted to the Middlesboro hospital; he had nervous symptoms, was easily moved to tears, and when he left the hospital became cruel to his wife and children. He came to Newcastle Infirmary, and on admission was sallow and looked much older than his age, with weakened memory and yellow sclerotics. His gait was unsteady. He had hyperæsthesia of the skin. He had a great flow of urine—fifty ounces—but there was neither albumen nor sugar in it. On analysis a large quantity of iron was found in the urine. His muscular power was greatly diminished, and there was incoördination. He had systolic murmur, and, five months after admission, universal jaundice. He died on March 16th. The lungs were found to be healthy. The liver was cirrhotic. The spleen was large, and weighed thirty-nine ounces. The brain was soft and œdematous. The portal blood entered the brain without passing through the liver. The symptoms rather resembled those of general paralysis of the insane.

Dr. Ralfe, of London, mentioned a somewhat similar case which he had treated in the Dreadnaught hospital of London.

Dr. Oliver mentioned similar cases, which resembled pernicious anæmia

Dr. Gairdner observed that, as yet, there was no clear proof that the products of digestion when impaired could cause the symptoms mentioned in this case.

Dr. C. R. Drysdale was inclined to ask whether this was not one of the cases with which he was pretty familiar, of syphilis of the liver and brain.

Dr. Drummond said that the occurence of syphilis had been denied by the man.

Dr. Thomas Oliver, of Newcastle-on-Tyne, read a paper on

A CASE OF TRAUMATIC EPILEPSY TREATED SUCCESSFULLY BY TREPHINING.

A boy, after a boisterous game, in which he had received a blow on the head, began to suffer from epileptic fits, and to complain of pain on the right temporal bone. Before and after each fit there was pain in this point, but the skin was quite healthy there. An aura was felt before the fits, which were extremely numerous. In many of the severer fits the left arm and leg were affected with paresis. When the fits were extremely bad, he was left stupid and dull, and on getting well he would write instead of speaking. Bromide and iodide of potassium were extensively tried, but were of no use. He was trephined by one of his surgical colleagues at the painful spot, and a piece of bone the size of a shilling was removed. The dura mater was apparently healthy, but by degrees it was noticed that it bulged out of the wound. A crucial incision was therefore made, and some serum exuded and drained away for a day. The patient had one or two minor fits, and then the wound healed up, and he had no fit at all for six months. He was then admitted again into the infirmary and remained there for some time, taking bromide of potassium, which cured the fits, from which he had now been free for some six months. Trephining was only indicated in traumatic epilepsy. Dr. Gowers had mentioned sixty cases of traumatic epilepsy.

Dr. Charlton Bastian said that the cases in which operations might be tried were those in which there were unilateral seizures, and in a few of these cases, doubtless, relief was obtained. In a case under his care, operated on recently by Mr. V. Horsley, in a child aged ten, there had been as many as thirty fits per diem, and bromides had done little or no good. There was a history of traumatism some five years previously. There was not much risk in these operations. In this case a square piece of bone was removed, and when this was done the dura mater looked healthy. An incision was made by Mr. Horsley, but nothing was found of importance. At first the boy was very much benefited by the operation, and his parents were much gratified. He had warned the father that the fits would probably return, and it appeared that they were now as bad as they had been.

Dr. Drummond said he had seen some cases which had been trephined by an enterprising surgeon, and observed that it was necessary to be most guarded in the prognosis of such cases. Many cases treated by large doses of bromides did not progress in any way.

Dr. Gairdner asked the question, "How long could bromide of potassium be exhibited without danger to the general health?" In one case he had been consulted by the parents of a young lady, aged eighteen. This patient had taken bromide of potassium for epileptic fits ever since she was of the age of three, and he had advised leaving off the drug, because the young lady had retardation of the menstrual flow, and he thought it a greater evil to have this retardation than to give doses for the epilepsy.

The President mentioned a successful case of trephining for epilepsy, carried out by Mr. Butcher, in Dublin.

Dr. Magee Finny, of Dublin, spoke of a case of epileptic coma treated by large doses of bromide of potassium fruitlessly. An incision was made in the right temporal region where the man had been struck, and the inner table of the skull was found to be depressed. This was raised and the man lost his epileptic fits. This resembled Sir T. Watson's famous case, mentioned in his lectures.

Dr. Nixon said that it was very important to delay the return of epileptic seizures as long as possible, and therefore, if any irritation was suspected, it should be removed at once. In one case he had recently had there was a marked history of syphilis, and the man rapidly recovered under doses of calomel, bromide and iodide of potassium.

Dr. Norman Kerr read a paper on the

RELATION OF ALCOHOLISM TO INEBRIETY.

The author said that the term alcoholism had been somewhat loosely employed. Some at random applied it to all moderate and immoderate drinking, or any kind of intoxication; others restricted it to the mental and moral, exclusive of the physical, phases of drunkenness. This probably arose through ignorance. Only of recent years had the existence of the disease inebriety been recognized. Alcohol was an irritant narcotic poison and the term alcoholism should be limited to the toxic phenomena directly or indirectly arising from the action of alcohol on body and brain. This included acute alcohol poisoning (fatal and non-fatal) and chronic alcohol poisoning, all the functional disturbances and tissue degenerations of various kinds, the vitiation of the blood, the circulatory tumult, the nervous perturbation, the vaso-motor paralysis (with or without unconsciousness) of transient alcoholic excitement, as well as the tremors of delirium tremens, the madness of "mania-a-potu," the depraved digestion, the cerebro-spinal paralysis, delusions, and insanity of more permanent and graver lesions. Under alcoholism would also be ranged the mental and moral depravities induced by alcoholic intoxicants, as well as the inherited proclivities to excess, brain irritability, and feeble will begotten of alcohol. Fatty and other degenerations of the liver, heart, kidneys, and other organs were also included. Inebriety, on the other hand, was a disease of the higher nerve-centres, allied to insanity, which might or might not be of alcoholic origin. This disease consisted in a morbid impulse to, or craze for, intoxication. The intoxicant consumed might be any narcotic. It was the immediate, the evanescent relief which was sought, the inebriates often hating the inebriating substances. Inebriety was, therefore, a true intoxication mania, or, as Dr. Kerr preferred to call it, narcomania, *i.e.*, a mania for narcotism. Inebriety, or narcomania, assumed various forms. There was alcohol, opium, chloral, chloroform, chlorodyne, ether, or cocaine inebriety. The disease might be constant or periodic, solitary or social, with periodicities of function, nerve energy, time, occupation, climate, season, etc. There were the inebrieties of insanity, of syphilis, and of other diseases, of convalescence from fevers, of heart apoplexy, of operations, of head or other injuries (traumatic inebriety), and of nerve-damage generally. The etiology and pathology of inebriety were of great importance to afford knowledge on which to base judicious treatment. Alcoholic trance, for example, was an obscure and extraordinary phenomenon, in which inebriates had awoke sometimes to full consciousness only to find themselves in a foreign country, though they had been able automatically to eat and talk and act like others around them. The alcoholic, therefore, was but one form of inebriety, which might be inherited or acquired. All drunkards were not diseased, though even these often became so in the long run. There was sometimes alcoholic inebriety without the graver symptoms of alcoholism, with no liver, heart stomach, or other bodily disturbance, the nervous disorder being the only ill health. There was thus alcoholic drunkenness with no true inebriety, and inebriety, or narcomania, with no actual intoxication by alcohol.

Dr. Isambard Owen read a paper on the

RESULTS OF THE COLLECTIVE INVESTIGATION COMMITTEE OF THE BRITISH MEDICAL ASSOCIATION'S INQUIRY INTO THE CONNECTION OF DISEASE WITH HABITS OF INTEMPERANCE.

The author read the memorandum which the Committee had addressed to the members of the Association, which was to the effect that few subjects among those which engage the attention of the profession at the present day are of greater importance than the question of the share taken by alcoholic drinks in the production of visceral disease, and of their influence on the causes and results of maladies in general. It is to be regretted that up to the present the stock of recorded facts open to the inquirer is far from being adequate to the gravity of the subject, our existing ideas being largely based on inferences from physiological experiment, or deductions from a limited number of cases, or on the general impressions of individual physicians. The Collective Investigation Committee believe that no work can more justly claim the attention of the members of the Association than an attempt to collect and combine, in as definite a manner as the nature of the subject admits of, the personal experience of the profession at large with reference to this very difficult question.

Those practitioners who were anxious to assist in this inquiry were invited to enter the deaths of their patients under one or other of the following five heads: Total Abstainers, Habitually Temperate Persons, Careless Drinkers, Free Drinkers, and Decidedly Intemperate Persons. These were numbered A, B, C, D, and E. The results in tabular form were that in Class A there were mentioned 122 deaths; in Class B, 1,529; in C, 977; in D, 547; in E, 603 deaths. With the spirit of compromise, distinctive of the day, 54 cases were included in a class called AB; 178, in BC; 112, in CD; 100, in DE, and 12 were unclassified. There were 4,234 cases of deaths returned. Among the deaths in Column E, while the average rate was 14.2 per cent., among professional men it was 9.5; among independent persons, 20.4; among clergymen it was 7.3; among mercantile, 13.8; among tradesmen, 16.9; among licensed victuallers, 40.2; artisans, 13.1; lumbermen, 10.9; drivers, 22.8; farmers, 10.2; soldiers, 25.5; sailors, 8.1; domestic servants, 20.8; and miscellaneous, 19.9. The average age at death for each class was, in Class A, 51 years 80 days; in B, 62 years 50 days; in C, 59 years 240 days; in D, 57 years 216 days; and in E, 52 years 14 days. The average age at death was thus, 58.92 years. With regard to the diseases in the various groups, there was a table showing the ratio between the cases falling in the lower and those in the higher half of the alcoholic scale, for the same forms of disease. This showed that between the ages of twenty-five and forty that ratio was, for phthisis, 1 to .7; for typhoid fever, as 1 to .7; for valvular disease of the heart, as 1 to .8; for chronic renal diseases, as 1 to 1.8; and for bronchitis, as 1 to 1.8. Between the ages of forty to sixty-five the similar ratios were, for malignant diseases, as 1 to .5; for phthisis, as 1 to 1; for valvular diseases, as 1 to 1.04; for pleurisy, as 1 to 1.09; for pneumonia, as 1 to 1.1; for bronchitis, as 1 to 1.1; for typhoid, as 1 to 1.1; for diseases of heart-wall, as 1 to 1.1; for apoplexy, as 1 to 1.2; for diabetes, as 1 to 1.3; for old age, as 1 to 1.5; for chronic renal disease, as 1 to 2.06; for cirrhosis, as 1 to 15.7. In the ages over sixty-five years of age, the ratios become for old age, as 1 to .36; for cystitis, as 1 to .39; for diarrhœa, as 1 to .4; for prostatic diseases, as 1 to .4; for bronchitis, as 1 to .4; for apoplexy, as 1 to .5; for malignant diseases, as 1 to .5; pneumonia, as 1 to .5; intestinal obstruction, as 1 to .5; disease of the heart-wall, as 1 to .6; disease of valves, as 1 to .7; chronic renal disease, as 1 to .7; nerve decay, as 1 to .7; phthisis, as 1 to .8; arterial degeneration, 1 to 1.1.

In the discussion which followed, Dr. Drummond, Dr. Cumming, Dr. Gairdner, and Dr. Kerr took part. It was admitted that the statistics were far too complicated to admit of any clear conclusion being drawn. Dr. Cumming said there was very little gout in Ireland. Dr. Gairdner remarked that some contended that phthisis was caused by alcohol, while others said it was cured by taking alcohol. This showed that the point was not by any means clearly made out.

Dr. Laffan then read a paper on

PLEURAL EFFUSION.

The author held that many cases of pleural effusions proved fatal early in the disease. One of the first difficulties arose from diagnosis, which was often very obscure. In some cases it was, as Dr. Allbutt had contended, impossible, unless by passing a needle. It was said by some that this plan might convert a serous into a purulent effusion. Failure to find the effusion was by no means unusual. If there were rigors and club-fingers this was an excellent diagnostic point. Effusions would persist indefinitely in some cases. He had, for instance, recently removed three gallons of effusion from a man in whom it had existed for five years. The indications for thoracentesis were (1) danger of asphyxia when the effusion was double; (2) abundance of the effusion; (3) purulence. He preferred a moderate size of aspirating needle, and operated usually in the back, in the lower scapular angle, not lower than the eighth interspace. The fluid should not be removed too rapidly, but gradually drain away by means of a stop-cock. Counter-openings were rarely required. In empyema four openings should be made. Death was sometimes caused by injections. Coma and pyæmia were sometimes the results of the operation. Operation should be early, before twenty-one days. It was not necessary to excise the rib. Anæsthesia was useful in many cases, but occasionally dangerous. Some persons objected to anæsthesia, but some patients suffered a good deal from the operation. There was, of course, danger of syncope. Cocaine and ether spray might possibly be useful in a few cases in place of ether or chloroform.

Dr. Drysdale, of London, had formerly been more a believer in the advantage of early thoracentesis than he now was. He thought it as well in adults to wait for five weeks before performing the operation, in order to give time for absorption to take place. In this remark he did not refer to children, since in these the disease was so frequently purulent.

Dr. Churchill preferred to open the eighth interspace in the back. It was often dangerous to puncture low, especially on the right side. Mr. Marshall taps as high as the fifth interspace in the axillary line. Nature sometimes in empyema opened in front as high as the fifth interspace; but he thought it was sometimes possible to improve on nature. He thought that thoracentesis should not be long delayed.

Mr. Boyd, of Dublin, said that sometimes physicians were rather too timid about drawing off the fluid in effusions into the pleura. He had operated one hundred and fifty times, without any bad results. His view was that, as soon as a large quantity of fluid was known to exist, it should be removed at once. The longer that fluid pressed on the lungs and thoracic viscera, the more dangerous it was to the general health. As to why the effusion in some cases became purulent, and not in others, he believed there was no real and accurate knowledge; all we knew was that about three-fourths of cases of effusion in children turned to empyema. In the adult, perhaps, bronchitis might help the formation of pus, but this was really not known. The best kind of aspirator was Potain's, which he used much at the Mater Misericordia Hospital. With regard to the resection of a piece of rib, which had been for a time advocated in London, he could only say he had done so twice, and in both cases the patient died, so that he considered this very bad practice. Cocaine, in his experience, was not

of any service locally. Freezing the part might occasionally succeed. A long drainage-tube was bad. A short one should be preferred. The situation of the incision was immaterial, provided it was not too low, for in that case the liver might be wounded.

The Section then adjourned.

THIRD DAY, AUGUST 5TH.

MR. ALFRED S. GUBB exhibited an "Apparatus for the Estimation of Urea," devised by Mr. Gerrard, Lecturer on Pharmacy at University College, London. This consisted of a **U**-tube, graduated in such a way as to show the quantity of nitrogen gas given off by a definite quantity of urine contained in a small bottle enclosed in a larger bottle containing the bromide solution. In the experiment shown, the urine contained half a per cent. of urea, so that it would contain about two and one-half grains per ounce of urine passed. The determination of the urea was extremely simple, and very rapidly performed.

DR. J. F. KNOTT, of Dublin, read a paper on "The Use of Certain Organic Acids in Rheumatic Gout and the Allied Diatheses."

DR. J. B. BOYD read a paper entitled "Remarks on Typhoid Fever, and on the Treatment by Liq. Sodæ Chloratæ, Bismuth, and other Drugs."

DR. RINGWOOD, of Kells, read a paper on "An Outbreak of Relapsing Fever."

DR. F. J. B. QUINLAN read a paper on the

TREATMENT OF ACUTE RHEUMATISM.

He said he had no long array of cases to bring before the Section, but would mention that blistering had been a common way of treating acute rheumatism. A large blister was sometimes put on the abdomen, partly covering the precordial region. When a blister had once been applied to a joint, that joint was not again affected. He had been accustomed to pay very great attention to the state of the heart in cardiac disease, because the patient did not feel pain there. With regard to the use of salicylate of soda, he had found it very depressing to the heart in many cases in which he had used it, and therefore he had quite recently used salicin in place of the soda salt, with very excellent results. Salicin, he remarked, is very cheap, and therefore of great service in hospital practice. It is so cheap that it has been used very extensively to adulterate quinine. He was aware that in London practice the evils of salicylate of soda were not seen; and he supposed this depended on a difference of race, just as the Scandinavian people could take so much more whiskey than the English or French races, or than the Italians or natives of Algiers.

DR. GILBERT SMITH, of London, had seen the evil effects of the salicylate mentioned by Dr. Quinlan in one case.

DR. GAIRDNER, of Glasgow, said he very rarely had had any bad effects from the salicylate of soda. He would match the Scottish Highlander even with the Norwegians in their endurance of the effects of alcohol.

DR. BASTIAN, of London, said he had treated all cases of acute rheumatism by salicylate of soda, and had found cases of endo- or peri-carditis rarely occurring. But patients may have relapses. As a general rule, the patients improved greatly from the use of the salicylate in from thirty-six to forty hours, and he gave from fifteen to twenty grains of the salt for a dose.

DR. CUMMING, of Belfast, mentioned two cases of hyperpyrexia occurring in his practice while the salicylate was being given, and which were not relieved by it. He tried twenty-grain doses of salicin, but this did not succeed, and finally had recourse to cold water applications, which did good. Opium was contraindicated. As to the influence of treatment on the prevention of heart disease he had noticed that under all forms of treatment the heart might become affected. The experience of all was that sodæ salicylate did not prevent relapses; and one of the great difficulties in treatment was that the patient removed himself away from the physician's care, and was seen no longer.

DR. DRYSDALE, of London, said he had not noticed any bad symptoms which he could put down to the use of sodæ salicylate. For a time he had tried salicylic acid; but it was not so satisfactory as the sodium salt. Occasionally cases of high temperature persisted in spite of the salicylate, and then the cold water plan was useful, and blistering was also sometimes of use in pericarditis.

DR. OLIVER said that in many cases the treatment by sodæ salicylate was not efficacious.

DR. NIXON, of Dublin, said he had always used sodæ salicylate with good results and had never had to give it up. He had not seen bad effects of opium in acute rheumatism. In very high temperature cases drugs would often fail, and in such cases the cold bath would prove serviceable. Quinine did not lower the pyrexia in such cases.

DR. ERNEST SANSOM read a paper on

METHODS OF PERCUSSION IN CARDIAC DISEASE.

A gentleman in active practice desires to have as little of his valuable time as possible occupied by each case; but he, Dr. Sansom, would plead for the possession of an accurate delineation of the heart in all cases of disease of that organ. In order to do this he had devised a vulcanite plexometer, by means of which he always mapped out the outline of the heart, and then by means of a brush he covered the points over with a pigment, and then put some tissue-paper over the cardiac region and took a copy of this percussion-map for preservation in his notebook. He had confirmed by many autopsies the accuracy of such maps. Again, as to the application of the sphygmograph and the cardiograph. The great value of the former is to show what effect pressure has on the pulse. Dr. B. W. Richardson's modification of Dudgeon's sphygmograph was an excellent sphygmograph. The cardiograph was not always so useful; but Pond's was the best. Anyone that pleased could adopt the graphic method to disease of the heart, and he greatly recommended them to do so.

DR. GAIRDNER, of Glasgow, wished to take the opportunity of congratulating Dr. Sansom on his accuracy in delineating the heart. He had gone to London to judge of his work and had found it quite excellent. Personally he had not carried out the method, but still used the finger as the plexometer.

DR. GILBERT SMITH, of London, said he also preferred the finger as a plexometer, and his finger was well suited to the purpose, as it was rather rheumatic and very sensitive to percussion, which made it a delicate plexometer.

DR. OLIVER, of Newcastle, said he agreed in Dr. Sansom's recommendations. He much approved of Dr. Richardson's instrument.

DR. DRYSDALE, of London, had tried Piorry's plexometer for many years, but much preferred the finger. As to mapping out the heart, that was a very hard matter in many cases.

DR. NIXON, of Dublin, much approved of the graphic methods described by Dr. Sansom.

NOVELISTS' MEDICINE.—Lady writers of fiction, as a rule, limit their literary eccentricities to excursions among amorphous elements of novelists' French and un-English grammar. They sometimes dose freely with poison and the dagger, but rarely venture on strictly anatomical details. The most unfortunate *lapsus calami*, however, which has come under our observation, is the following: The hero, with great difficulty, has succeeded in saving the heroine from falling over a precipice. The lady has fainted and is apparently lifeless, but the hero finds, to his intense relief, "by the pulse in her *femoral* artery," that her heart still beats.—*Bristol Medico-Chirurgical Journal.*

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 21 to August 27, 1887.

TREMAINE, W. S., Major and Surgeon. Found incapacitated for active service by an army retiring board, and extension of leave of absence on account of sickness still further extended until further orders. Par. 9, S. O. 192, A. G. O., August 19, 1887.

BARTHOLF, JOHN H., Major and Surgeon. Leave of absence extended one month. Par. 7, S. O. 196, A. G. O., August 24, 1887.

PATZKI, JULIUS H., Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 15, S. O. 195, A. G. O., August 23, 1887.

MATTHEWS, WASHINGTON, Captain and Assistant Surgeon. Ordered to proceed to Phœnix, Ariz. Ter., on public business, and on completion thereof to return to his proper station. S. G. O., Par. 21, S. O. 195, A. G. O., August 23, 1887.

TAYLOR, BLAIR D., Captain and Assistant Surgeon. Granted leave of absence for twenty days, to take effect on or about August 31, 1887. Par. 7, S. O. 193, A. G. O., August 20, 1887.

SWIFT, E. L., First Lieutenant and Assistant Surgeon. Ordered to report in person to Commanding General, Division of the Pacific, for duty with troops at Round Valley, Indian Reservation. Par. 20, S. O. 195, A. G. O., August 23, 1887.

Medical Items.

DRY HOT-AIR BATHS FOR SYPHILITIC PATIENTS.—Dr. Stepanoff, of Moscow, has contrived a plan of treating patients suffering from syphilis which has resisted mercurial and iodine treatment. He has had a box or bath constructed with an iron bottom lined with thick felt, in which the patient is placed. The bath is heated to about 170° to 190° F. by means of two Bunsen lamps, each consisting of five burners. After the patient has been "baked," he is put to bed and covered with blankets, so as to prolong the sweating process commenced in the bath for an extra half-hour. After this he is allowed to dress and go into the ward to his dinner. By means of these baths the mercury is rapidly eliminated from the system, and the patient's condition greatly improves, and after a course mercury is found to act quickly and energetically.

EXTIRPATION OF RUPTURED UTERUS.—Dr. Andrews writes as follows in the *Lancet*: "On September 12th, at 5.30 P.M., one of the externe midwifery attendants was called in to attend the fifth labor of Mrs. S——, who was said to have had pains for twenty-four hours. She was a delicate woman of short stature and her previous confinements had all been normal. Vaginal examination showed the os fairly dilated, membranes unruptured, and the vertex presenting resting on the pubes. The pains were of medium frequency, and apparently those of the first stage of labor. At 6.30 P.M., the pulse being then about 120, the membranes ruptured and the pains increased in force and frequency, culminating about 8 P.M. in exceedingly strong expulsive efforts, which affected the progress of the head but little, if at all. Immediately after these the patient complained of intense pain in the stomach, there was marked collapse, and all labor pains ceased. I was now summoned to the case, and found the patient nearly pulseless, pale, and exhausted, but quite conscious, and the head on the brim of the pelvis and rather movable. Recognizing the urgent necessity for immediate delivery, I directed the abdomen to be well supported by the externe, introduced the long forceps, and proceeded to deliver the child. No difficulty was experienced in the introduction of the blades, and but very gentle traction was required. Fearing that the perineum might rupture, I withdrew the forceps as soon as the head was well down upon it, but instead of expulsion taking place, the head receded into the vagina. I again applied the forceps and delivered without further difficulty. The child was a large one, weighing nine and one-half pounds, was still-born, and the delivery was followed by a gush of blood, though the uterus appeared firmly contracted. After waiting a few minutes, finding that the placenta did not come away, I introduced my hand and found that it passed through a rent in the uterine wall into the abdominal cavity. Following up the cord with my fingers, I discovered the placenta in the abdominal cavity above the uterus, and removed it without difficulty. An injection of two-thirds of a grain of ergotine was now administered. The pulse was quite imperceptible and the patient apparently dying. An hour later the patient had rallied considerably; the pulse was 140, of fair force, and there had been no further hemorrhage from the vagina. About 10.30 P.M., however, the pulse was much feebler, and coils of intestine had come down through the rent into the vagina. On consultation it was agreed that the patient's only chance lay in the immediate performance of abdominal section. Ether was accordingly administered, and I proceeded to open the abdomen by an incision in the median line extending from a quarter of an inch below the umbilicus to a quarter of an inch above the pubes. I found a large, ragged tear in the left and front of the organ, while the abdominal cavity contained a very large quantity of blood. The position and extent of the rent, together with the extreme laceration and thinning of its edges, determined me to remove the entire uterus and appendages rather than attempt to unite the tear with sutures. I accordingly lifted the uterus out through the abdominal wound, placed a double ligature round both broad ligaments, and divided them. Then carefully clamping the cervix below the rent, I transfixed the pedicle with a needle and tied each half with a double ligature, afterward carrying one of the ends round the whole stump. Cutting through the pedicle above the clamp, I now removed the uterus. The peritoneal cavity was sponged out as completely as possible, and the pedicle brought forward and fixed with harelip pins to the lower end of the abdominal wound. I then closed the upper part of the incision with wire sutures and applied the usual gauze dressings. During the whole operation, which lasted three-quarters of an hour, there was but very little hemorrhage, and during the earlier stages the patient's condition was all that could be desired. Toward the end, however, she gradually sank, and died soon after the operation was completed. Subsequent examination of the uterus showed the organ to be of the normal size after parturition, and weighing roughly twenty-four ounces. The rent extended from the attachment of the upper part of the left broad ligament vertically downward to the lower third of the cervix, and then passed transversely across the anterior cervical wall to the right side, its total length being nearly six inches and a half. The edges were much lacerated and very thin, and in the surrounding tissue there was a good deal of blood extravasated. The placental site was on the fundus and posterior wall, and the muscular tissue was firm and well contracted, showing a healthy structure on microscopic examination."

THE INFLUENCE OF TEA, COFFEE, AND COCOA ON DIGESTION.—Dr. Fraser has recorded the results of an interesting series of experiments on the action of our common beverages on stomachic and intestinal digestion. The experiments have been most carefully arranged from a physical standpoint, and give us some valuable hints on the digestion of the chief alimentary principles, but

they have no bearing, it should be mentioned, on individual variations of human digestion, or on the influence of the various glands in preparing the gastric or intestinal juices (*The Lancet*). They are, however, of much value in showing how standard preparations of the peptic and pancreatic ferments are modified in action when our ordinary daily beverages are allowed their free action on the digestion of various articles of food. The digestive processes were carefully investigated, and absorption was imitated by a proper dialyzing arrangement. An artificial peptic juice, and afterward an artificial pancreatic juice, were employed, and the amount of nitrogenous matter dialyzed was most carefully estimated. The food-stuffs experimented on were raw and cooked serum and egg albumens, raw and cooked myosin, syntonin, alkali albumen, casein, gluten, starch, and oleine. The results obtained from an exhaustive series of experiments and analyses show that all the three typical infused beverages—tea, coffee, and cocoa—retard the digestion and absorption of all the nitrogenized proximate principles of dietetic substances when peptic and pancreatic digestion are taken together, and that they uniformly retard peptic digestion, although tea may assist the diffusion of peptones from the stomach. Pancreatic digestion is also uniformly retarded, and diffusion thereafter is but rarely assisted, so that neither of them compare advantageously with water as a standard beverage for experimental investigations. A summary of dietetic advice is added to Dr. Fraser's observations, which will, in the main, agree with that which is now given by our best authorities in cases of dyspepsia; and we are glad that experimental inquiries afford so strong a basis of support to empirical clinical observations: "1. That it is better not to eat most albuminoid food-stuffs at the same time as infused beverages are taken, for it has been shown that their digestion will in most cases be retarded, though there are possibly exceptions. Absorption may be rendered more rapid, but there is a loss of nutritive substance. On the other hand, the digestion of starchy food appears to be assisted by tea and coffee; and gluten, the albuminoid of flour, has been seen to be the principle least retarded in digestion by tea, and it only comes third with cocoa, while coffee has apparently a much greater retarding action on it. From this it appears that bread is the natural accompaniment of tea and cocoa when used as the beverages at a meal. Perhaps the action of coffee is the reason why, in this country, it is usually drunk alone or at breakfast, a meal which consists much of meat, and of meats (eggs and salt meats) which are not much retarded in digestion by coffee. 2. That eggs are the best form of animal food to be taken along with infused beverages, and that apparently they are best lightly boiled if tea, hard boiled if coffee or cocoa, is the beverage. 3. That the casein of the milk and cream taken with the beverages is probably absorbed in a large degree from the stomach. 4. That the butter used with bread undergoes digestion more slowly in presence of tea, but more quickly in presence of coffee or cocoa; that is, if the fats of butter are influenced in a similar way to oleine. 5. That the use of coffee or cocoa as excipients for cod-liver oil, etc., appears not only to depend on their pronounced tastes, but also on their action in assisting the digestion of fats."

Scars Following Skin Diseases.—In an article in the *Polyclinic*, Dr. Van Haslingen thus concludes a discussion of the various forms of skin disease which are followed by more or less disfiguring scars: Cysts, wens, the deeper forms of dermatitis, furuncle, anthrax, herpes zoster, acne, ecthyma, and tinea favosa may at times and under certain circumstances give rise to the formation of scars. Scrofuloderma and syphiloderma in some forms, the various forms of lupus, carcinoma, and sarcoma almost inevitably lead to scarring. Another class of diseases which may indirectly, though not directly, give rise to scars through scratching are the pruriginous affections *par excellence*, *i.e.*, pruritus and eczema. These may be followed by cicatrices and other results of scratching, when the lesions themselves might not leave anything which could be called a cicatrix. With these facts in mind, the physician can often soothe the fears of anxious patients their parents, and friends by assuring them that threatening lesions, with profuse discharge and piled-up crusts, will not eventuate in scarring. One point may be remembered in this connection, and that is, that when we have crusts of dried serum and serous discharge only, we rarely have scars following, while lesions resulting in the exudation of pus are not unfrequently followed by cicatricial reparation.

Persistent Yawning and Sneezing after the Extraction of a Tooth.—A case of a somewhat remarkable character is at the present time in the London Temperance Hospital, under the care of Dr. R. J. Lee. A girl, aged fifteen, had the last molar tooth in the lower jaw on the right side removed about six weeks ago. No anæsthetic was administered. She was in perfect health at the time. Half an hour after the operation she began to yawn, and has continued to do so constantly since. One yawn succeeds another without interruption, and with an interval of two or three seconds. Galvanism had been tried without effect, and other remedies previous to admission into the hospital. Three days afterward the yawning changed to sneezing, and recently she has suffered from constant and rapidly succeeding fits of sneezing, each of which paroxysms appears to begin with a yawn. She seems to have no power of controlling herself, or only to a very slight extent; and if she attempts to do so, the next sneeze is more violent.—*The Lancet*, July 23, 1887.

Abnormality of the Neck.—Dr. J. B. Muirhead reports, in the *British Medical Journal*, July 23, 1887, the following curious condition in a child, aged five weeks, healthy and otherwise well-formed: Extending from below the left ear to the left upper corner of the sternum is a firm, broad strip of cartilage, probably already ossified in part, resembling in shape and size the sternomastoid muscle, but presenting a forward projection in the middle of the neck, as if bent at an obtuse angle. It may be caught between the finger and thumb, and moved freely from right to left. The cartilage is perfectly separate from the jaw above and from the clavicle below it, and seems to have no other connections except those described. Its origin from the temporal bone is immediately below and within the left auricle, about half an inch in front of the normal origin of the sternomastoid muscle. The probability is thus suggested that its upper attachment is connected with the styloid process. Its connection with the sternum occupies the position of the insertion of the sternal portion of the sternomastoid muscle.

Unusual Symptoms from Quinine.—Dr. Tsoukales reports in *Galenos* of June 20, 1887, the case of a man of healthy antecedents, to whom he gave twenty grains of sulphate of quinine in divided doses for a fever accompanying a severe attack of laryngitis. A short time after taking the first dose the man began to complain of a feeling of formication and numbness of the scrotum and penis. This passed off in a few minutes, and was followed by an intense itching, which persisted for about three days. The dartos of the scrotum was strongly contracted, the skin being drawn into tight folds. When the itching subsided, it was succeeded in some parts by a branny desquamation, but chiefly by fissures running parallel with the median raphé from the root of the penis to the perineum. These fissures also formed on the glans from the meatus to the corona. There was at first some bleeding from the cracks and then a purulent secretion. After the itching ceased the patient complained of pretty severe pains in the testicles. The fissures were healed, after the application of drying powders, in about a week. A week later another dose of quinine was given, and was followed by the same phenomena.

The Medical Record

Vol. 32, No. 11. NEW YORK, SEPTEMBER 10, 1887 Whole No. 879

Reports of Societies.

International Medical Congress.

NINTH SESSION.

Held in Washington, D. C., September 5, 6, 7, 8, 9, *and* 10, 1887.

(Special Report to THE MEDICAL RECORD.)

MONDAY, SEPTEMBER 5TH—FIRST DAY.

THE Congress assembled in Albaugh's Opera House, and was formally opened at 11 A.M. by His Excellency GROVER CLEVELAND, President of the United States, who said: "I feel that the country should be congratulated to-day upon the presence at our capital of so many of our own citizens, and those representing foreign countries who have distinguished themselves in the science of medicine, and are devoted to its further progress. My duty in this connection is a very pleasant and a very brief one. It is simply to declare that the Ninth International Medical Congress is now open for organization and for the transaction of business."

DR. HENRY H. SMITH, of Philadelphia, Chairmain of the Executive Committee, next named the following

OFFICERS OF THE CONGRESS.

PRESIDENT—Nathan Smith Davis, M.D., LL.D., of Chicago, Ill.

VICE-PRESIDENTS—McCall Anderson, M.D., F.F.P.S., Glasgow; Thomas Annandale, M.D., F.R.C.S. (Edin.), M.R.C.S. (Eng.), Edinburgh; Docteur Dujardin-Beaumetz (honorary), Paris; Cuthbert Hilton Golding-Bird, M.D., F.R.C.S., London; Professor Carl Braun, M.D., Vienna; William Brodie, M.D., Detroit, Mich.; John Chiene, M.D., F.R.C.S., Edinburgh; George Joseph Hamilton Evatt, M.D., L.R.C.S., East Indies; Sir B. Walter Foster, M.D., F.R.C.P., Birmingham, England; Mr. Ernest Hart, M.R.C.S., London, England; Mr. Jonathan Hutchinson, F.R.C.S., London, England; George Murray Humphrey, M.D., F.R.C.S., Cambridge, England; Sir Thomas Longmore, C.B., F.R.C.S., Netley, England; Frederick B. Jessett, F.R.C.S., London, England; Sir William Gull, M.D., LL.D. (Cantab.), F.R.S., D.C.L. (Oxon.), London, England; William Wirt Dawson, M.D., Cincinnati, O.; Thomas Michael Dolan, M.D., F.R.C.S. (honorary), Halifax; Thomas Richard Fraser, M.D., F.R.S., Edinburgh, Scotland; James A. Grant, M.D. (honorary), Ottawa; James Andrew S. Grant, M.D., LL.D., Bey (honorary), Cairo, Egypt; A. L. Gusserow, M.D., Berlin, Germany; Dr. Hans Ritter von Hebra, Vienna; Thomas John Maclagan, M.D., M.R.C.P., London, England; Sir Douglas Maclagan, M.D., F.R.C.P., Edinburgh, Scotland; Withers Moore, M.D., F.R.C.P. (London), M.R.C.S., Brighton, England; John Marshal, F.R.C.S., London, England; Morell Mackenzie, M.D., M.R.C.S., London, England; Sir Henry Thompson, F.R.C.S., London, England; Sir William Roberts, M.D., F.R.C.P. (London), F.R.S., Manchester, England; George B. Macleod, M.D., F.R.S., Glasgow, Scotland; John S. McGrew, M.D., Honolulu; Edward M. Moore, M.D., LL.D., Rochester, N. Y.; Karl von Mosengeil, M.D., Bonn, Germany; Professor W. D. Müller, Berlin, Germany; Wm. Murrell, M.D., M.R.C.S., London, England; Chas. D. F. SECRETARY GENERAL — John B. Hamilton, M.D., Washington, D. C.

ASSOCIATE SECRETARIES—William B. Atkinson, M.D., Philadelphia, Pa.; George Byrd Harrison, M.D., Washington, D. C.; Frank Banga, M.D., Chicago, Ill.

TREASURER—E. S. F. Arnold, M.D., M.R.C.S., Newport, R. I.

Chairman of the Finance Committee — Richard J. Dunglison, M.D., Philadelphia, Pa.

Chairman of the Executive Committee — Henry H. Smith, M.D., LL.D., Philadelphia, Pa.

Chairman of the Committee of Arrangements—A. Y. P. Garnett, M.D., Washington, D. C.

PRESIDENTS OF SECTIONS—Section I. General Medicine—Abraham B. Arnold, M.D., Baltimore, Md.

Section II. General Surgery—William T. Briggs, M.D., Nashville, Tenn.

Section III. Military and Naval Surgery and Medicine—Henry H. Smith, M.D., LL.D., Philadelphia, Pa.

Section IV. Obstetrics—De Laskie Miller, M.D., Ph.D., Chicago, Ill.

Section V. Gynecology—Henry O. Marcy, M.D., Boston, Mass.

Section VI. Therapeutics and Materia Medica—Traill Green, M.D., LL.D., Easton, Pa.

Section VII. Anatomy—William H. Pancoast, M.D., Philadelphia, Pa.

Section VIII. Physiology—John H. Callender, M.D., Nashville, Tenn.

Section IX. Pathology—Alonzo B. Palmer, M.D., LL.D., Ann Arbor, Mich.

Section X. Diseases of Children—J. Lewis Smith, M.D., New York, N. Y.

Section XI. Ophthalmology—Julian J. Chisolm, M.D., Baltimore, Md.

Section XII. Otology—Samuel J. Jones, M.D., LL.D., Chicago, Ill.

Section XIII. Laryngology—William H. Daly, M.D., Pittsburg, Pa.

Section XIV. Dermatology and Syphilography—Andrew R. Robinson, M.D., New York, N. Y.

Section XV. Public and International Hygiene—Joseph Jones, M.D., New Orleans, La.

Section XVI. Climatology and Demography—Albert L. Gihon, M.D., U. S. Navy.

Section XVII. Psychological Medicine and Nervous Diseases—Judson B. Andrews, M.D., Buffalo, N. Y.

Section XVIII. Dental and Oral Surgery—Jonathan Taft, M.D., Cincinnati, O.

REPORT OF THE SECRETARY-GENERAL.

Mr. President: According to the precedent set at former sessions of this body, the Secretary-General must make a report of the work performed since the session last preceding, but I will only occupy the time of the Congress for the briefest possible space.

It is now a matter of history that in May, 1884, the American Medical Association met in this capital, and passed a resolution inviting the Congress to honor America by holding its next session in the United States.

At the meeting in Copenhagen, in August, 1884, when the question came up for disposition, Washington was selected. The committee, having borne the invitation and secured its acceptance, returned home, and immediately began the work of organization, and shortly before the meeting of the American Medical Association in New Orleans, in May, 1885, they completed the preliminary organization. But it transpired that this committee were unable to frame an organization satisfactory to the majority of the members of the Association, and, after some discussion, a resolution was adopted which authorized the appointment of additional members of the committee, and, in accordance with our American system of representation, the committee consisted of one member from each State and Territory of the Union, to which was added one representative from each of the three public medical services, and these new members were elected by the State and Territorial delegations. The enlarged committee met in Chicago a few weeks after the New Orleans meeting of the American Medical Association, and several of the members of the first committee were present and acted harmoniously with the committee. In a short time, however, each of the original committee had withdrawn, and the management was thus deprived of their experienced and valued services. The committee have, therefore, had to contend against more than the ordinary difficulties attending so great an undertaking, and its present success is due entirely to the zeal and energy of its chairman, Professor H. H. Smith, of Philadelphia, and the unflagging interest and industry of the remaining members of the committee.

Dr. A. Y. P. Garnett, of Washington, D. C., Chairman of the Local Committee of Arrangements, then announced

THE ARRANGEMENTS FOR THE SOCIAL ENTERTAINMENT OF THE MEMBERS OF THE CONGRESS AND THEIR FAMILIES.

THE ADDRESS OF WELCOME

was delivered by Hon. Thomas F. Bayard, Secretary of State. In the name of his fellow-countrymen he expressed gratification at the visit of the delegates to Washington. The world is becoming acquainted and international intimacy is growing; a spirit of common brotherhood is increasing so that the word "stranger" will soon be obliterated from the vocabulary of civilization. If letters constitute a republic, science is a democracy. In the United States individual enterprise has produced great scientific institutions without the aid or interference of government. The proceedings of the Congress will be watched with interest by the sixty million people of this country.

RESPONSES

were made by the following gentlemen:

Dr. William H. Lloyd, of the Royal Navy; Dr. Léon Le Fort, of France; Professor Unna, of Germany; Professor Semmola, of Italy; Dr. Charles Reyher, of Russia.

Dr. Lewis A. Sayre, of New York, occupied the chair during the delivery of

THE ADDRESS OF THE PRESIDENT OF THE CONGRESS.

Dr. Davis began by paying an eloquent tribute to the memory of Austin Flint, M.D., LL.D., and continued as follows:

With a full consciousness of my own deficiencies, and still with a heart overflowing with gratitude, I thank you for the honor you have bestowed in selecting me to preside over the deliberations of this great and learned assembly. It is an honor that I appreciate as second to no other of a temporal nature because it has been bestowed, neither by conquest nor hereditary influence, nor yet by partisan strife, but by the free expression of your own choice.

The living human body, the chief object of your solicitude, not only combines in itself the greatest number of elementary substances and the most numerous organs and varied functions, so attuned to harmonious action as to illustrate the operation of every law of physics, every known force in nature, and every step in the development of living matter, from the simple aggregation of protoplasm constituting the germinal cell to the full-grown man, but it is placed in appreciable and important relations with the material objects and immaterial forces existing in the world in which he lives.

Hence a complete study of the living man, in health and disease, involves a thorough study, not only of his structure and functions, but more or less of every element and force entering into the earth, the air, and the water, with which he stands in constant relation.

The medical science of to-day, therefore, embraces not only a knowledge of the living man, but also of such facts, principles, and materials gathered from every other department of human knowledge as may increase your resources for preventing or alleviating his suffering and of prolonging his life.

The time has been when medical studies embraced little less than the fanciful theories and arbitrary dogmas of a few leading minds, each of which became for the time the founder of a sect or so-called school of medicine, with his disciples more or less numerous. But with the development of general and analytical chemistry, of the several departments of natural science, of a more practical knowledge of physics, and the adoption of inductive processes of reasoning, the age of theoretical dogmas and of medical sects blindly following some

more plausible leader passed away, leaving but an *infinitesimal* shadow yet visible on the medical horizon.

The address closed with an appeal for the collective investigation of the phenomena of disease.

The Congress then adjourned.

SECTION IN ANATOMY.

WILLIAM H. PANCOAST, M.D., PHILADELPHIA, PA., PRESIDENT.

Secretaries—Dr. John J. Berry, Portsmouth, N. H.; Dr. William C. Wile, Danbury, Conn.; Dr. C. Remy, Paris, France.

MONDAY, SEPTEMBER 5TH—FIRST DAY—AFTERNOON SESSION.

The President's Address was postponed to the second day.

The first paper read was by J. M. MATTHEWS, M.D., of Louisville, Ky., on

THE ANATOMY OF THE RECTUM AND ITS RELATION TO REFLEXES.

He began by reviewing the anatomical bearings of these parts, which he thought had been much neglected. He thought that the reflexes had not been sufficiently considered, and spoke of the difficulty with which these parts were brought under the influence of an anæsthetic on account of their extensive nerve supply. He spoke of the many causes of constipation causing congestion of the mucous membrane and reflex spasm of the sphincter muscle. He related cases showing the large number and variety of symptoms rectal irritation could produce, and particularly a case of obstinate constipation simulating locomotor ataxia. He also dwelt upon the importance of examining the rectum in certain cases of constipation, and of exploring it high up.

DR. GERVAIS, of Belgium, said he had seen many cases of reflex irritation from the rectum. He asked if injections of carbolic acid were practised both for external and internal hæmorrhoids.

DR. F. C. SCHAEFER, of Chicago, Ill., reported having seen cases in which most excruciating pain through the perineum had been removed by simply relieving the constipation, showing the reflex character of the pain.

DR. WILLIAM C. WILE, of Danbury, Conn., related a case of hæmorrhoids from which the patient had become insane. The insanity was cured shortly after removing the hæmorrhoids.

DR. ALBERT B. STRONG, of Chicago, Ill., mentioned a very severe case of gonorrhœa in his practice which was only cured after some existing piles had been removed.

DR. GALLET, of Belgium, had witnessed cases similar to those related by Dr. Matthews.

DR. J. M. MATTHEWS, of Louisville, Ky., further stated that he did not spare the knife in operations for the removal of hæmorrhoids, but preferred it to all other means in its proper place. He spoke of the dangers attending the injection of carbolic acid. He laid great stress upon the point that pruritus ani should not be treated as a disease, but as a symptom, the cause of which must first be removed to effect a cure.

THE PRESIDENT mentioned an instrument which he had used for some time for the treatment of rectal stricture. This instrument, which he had not yet exhibited before any society, consisted of a rectal sound formed on anatomical principles to conform to the curved direction of the rectum. He dwelt upon the importance of the proper curves in this instrument.

DR. AMBROSE L. RANNEY, of New York, then read a paper entitled,

DOES A RELATIONSHIP EXIST BETWEEN ANOMALIES OF THE VISUAL APPARATUS AND THE SO-CALLED NEUROPATHIC TENDENCY?

He thought that the neuropathic tendency was an important factor as a cause of the largest mortality. He was of the opinion that many neuroses were caused by an eye defect. He quoted from the statistics collected by Dr. George Stevens, of New York, and from his own carefully studied one hundred cases. His deductions were as follows:

1. No one has yet shown in what this predisposition lies; hence it can be shown that eye defect is an important element in these conditions.

2. There is no recognized pathology in functional nervous diseases. The view that they are constitutional diseases is by no means established by pathological research.

3. Heredity is very common in these affections. It is one of the most marked features in this class of nervous diseases.

4. My records go to show that eye defects are found in a very large proportion of such subjects.

5. Many of the eye defects found can be shown to be congenital, being inherited like other peculiarities.

6. The manifestations of the neuropathic predisposition vary with each case. They are called forth often by extremely trivial causes. These accidental circumstances or simple coincidences are too frequently recorded as of great clinical interest.

Dr. Ranney tested all eyes with a four per cent. solution of atropine. He quoted many cases, principally of epilepsy and melancholia, which had been under the care of the best neurologists, and which had been cured by correcting errors of vision. He believed that there was absolutely no cases of migraine without eye defect. He said he could cure seventy-five per cent. of such cases.

DR. PIERCE, of Ohio, cited cases of chorea caused by fright, and cases in which the chorea had been cured and in which squint continued.

DR. WILLIAM C. WILE, of Danbury, Conn., then read a paper entitled

WHICH SHALL BE THE SITE OF A URINARY FISTULA?

in which he appealed to the Section to decide the question. He cited a case in which a very hypertrophied prostate gland made the operation of entering the bladder exceedingly difficult.

THE PRESIDENT said he was not at all afraid of the prostate gland, but treated it as a foreign body when operating.

The Section then adjourned.

SECTION IN DERMATOLOGY AND SYPHILOGRAPHY.

A. R. ROBINSON, M. D., NEW YORK, PRESIDENT.

Secretary—Dr. William S. Gottheil, New York.

MONDAY, SEPTEMBER 5TH—FIRST DAY—AFTERNOON SESSION.

THE PRESIDENT opened the Section with a few general remarks, and then read his opening address. He called attention to the inadequacy of the course of study in our American medical schools, necessitating a trip to Europe to perfect one's self in dermatology and other specialties. He regarded it as an error to combine in our medical schools the study of dermatology with genito-urinary diseases, rather than with general internal pathology, which holds such a close etiological relationship to many cutaneous diseases. The knowledge of dermatology obtained in other languages is apt to influence the student in his future course of study and in his practice. That there are no American views of dermatology and no American school is to be greatly regretted. It is not possible to learn dermatology in this country except under great disadvantages. He called attention to the serious evil of indiscriminate medical writing and compilation to the neglect of original work, the proportion of papers representing original research being noticeably low.

Dr. William Welch, of Philadelphia, Pa., read a paper on

VACCINATION DURING THE INCUBATION PERIOD OF VARIOLA.

The author endeavored to show that vaccination during the incubation period of variola has, at least in his own hands, given gratifying results, preventing or modifying the small-pox eruption. The contrary view he believes to be unsupported by facts and not tenable.

Vaccination during the initial stage is valueless. If it be performed very early in the incubation stage it exerts a modifying influence and may prevent the attack altogether.

Vaccinia does not begin to exert its effect until the formation of the areola about the vesicles.

It must not be long delayed after the contagion has been received in the system if favorable results are expected. The character of the vesicle has much to do with the protection secured. When the vesicles are imperfectly formed or retarded the efficacy is to be feared. Animal lymph is too unreliable. Fresh, eighth-day lymph, from a typical vaccine vesicle, is to be preferred.

By numerous insertions of the virus we are more sure of good results. He had no doubt the process of vaccinia is hastened by multiple insertions.

He has made observations upon 144 cases, from which he has been led to believe that vaccination in the incubation period gives a certain immunity from variola.

Dr. Cundell Juler, of Cincinnati, O., said, he believed that the lymph from the vesicle itself gave an immunity which the crust did not, and when used he did not consider revaccination necessary, but with the crust it was. The lancet should be kept scrupulously clean.

Dr. Rogers Parker, of Liverpool, England, a public vaccinator for the city of Liverpool, said that in the large cities of England human lymph was usually employed. Large vaccination stations were established, to which the parents were required to bring the children at certain times, and the children vaccinated one week returned upon the same day the next week, so that there was always an abundance of vesicles from which to choose in vaccinating the others. Revaccination is not compulsory, but was usually done in schools and public bodies at about the age of fourteen.

Dr. Gottheil, of New York, said that he had frequently noticed a fungating sore about two weeks after vaccination, which he had regarded as a weak ulcer. With some sets of lymph it always appeared, and with others never.

Dr. Keller, of Hot Springs, Ark., related an incident of war times. He was in charge of a hospital on the Southern side. An epidemic of variola broke out. A supply of lymph was received, with instructions that it came from the North, and was suspected of being poisoned. Such stories were then current. He decided to use it, and, to avoid error, divided each point, vaccinating a citizen with one part and a soldier with the other. Nine-tenths of the soldiers had unhealthy sores following the operation, but none of the citizens, showing that they were due to the scorbutic condition of the soldiers, and not to impure virus.

Dr. Yeamans, of Detroit, Mich., said his belief in the protective power of vaccination, after exposure had occurred, grew yearly less and less. He had had considerable experience in the matter, and thought we lost sight of the many other influences brought to bear, which may modify the case under observation.

Dr. Lathrop, of Dover, N. H., believed that he had seen vaccinia take the place of small-pox.

Dr. Robinson, the President, asked why, if vaccinia depended on micro-organisms, which multiply so rapidly, more than one point of inoculation was necessary?

Dr. Welch, in closing, said he had been sceptical in regard to the necessity for multiple inoculations, and believed one typical cicatrix gave as good protection as many. Animal virus, or virus of recent humanization, gives a more durable protection. That of long humanization produces a more superficial scar, and deaths were more frequent in those showing superficial scars. He does not believe in life-long protection of vaccination. The ulcers mentioned by Dr. Gottheil he thought were only found after animal lymph had been used. It is not true vaccination, and it gives no protection.

RECTAL ALIMENTATION IN DISEASES OF THE SKIN.

Dr. J. V. Shoemaker, of Philadelphia, Pa.: All substances in solution are speedily absorbed by the rectum. Medicines in the form of suppositories and powders are taken up more slowly, but are cleanly and easy of administration.

In lupus of the mouth and lips, after scraping, the rectal method of alimentation and medication is recommended.

Pemphigus and impetigo in children of all ages are often due to alimentary disturbance, in which this method has advantages over the administration of food and medicines by the mouth.

Acne due to stomachic irritability, with vomiting, nausea, etc., can be cured in from two to four weeks by giving milk and other nutritious enemata per rectum, care being taken to insure retention. They should be lukewarm, and given only once every four hours.

Rectal medication is of value in those to whom medicines by the mouth are distasteful.

In many cases of syphiloderm the eruption disappears after suppositories of five grains of calomel or a fraction of a grain of the protiodide.

Scrofuloderma can be cured by rectal enemata of cod-liver-oil, when it cannot be taken by the mouth.

Urticaria can at times be best relieved by an enema of an ounce each of castor-oil and glycerine.

Pruritus ani treated by suppository of powdered geranium in ten-grain doses acts well.

Arsenic and antimony are of great benefit in some cases of psoriasis, but they may disorder the stomach. They can then be given with care by suppository.

Iodide of potassium in small doses, in the form of suppository, prevent many disagreeable symptoms produced by this drug.

Dr. H. G. Unna, of Hamburg, Germany, agreed with the reader of the paper in the good effects obtained by rectal medication in many affections. He asked concerning the experience of the author in regard to the administration of mercury. Whether diarrhœas and other unfortunate effects were not likely to occur.

Dr. Klotz would be afraid that the absorbent power of the rectum would be lowered in certain cases. For example, in pemphigus in children he would be afraid that the method would fail, as in other febrile diseases.

In closing, Dr. Shoemaker replied to Dr. Unna's question that when the mercurial was given first in small doses and gradually increased, the good effects were secured and the ill effects obviated.

Dr. H. Klotz, of New York, read a paper

ON THE OCCURRENCE OF ULCERS RESULTING FROM SPONTANEOUS GANGRENE OF THE SKIN, DURING THE LATER STAGES OF SYPHILIS, AND THEIR RELATIONS TO SYPHILIS.

Whenever we find a round-shaped, punched-out ulcer, with thickened, abrupt edges involving the entire thickness of the skin, with uneven floor, and a dark-green color, in a person with syphilis in its later stages, we generally consider it a syphilitic ulcer, and most frequently due to the breaking down of gummatous infiltration. The author's observations have led him to believe that similar ulcers in syphilitics may result directly from circumscribed spontaneous gangrene of the skin. The cases have occurred mostly in dispensary practice, and the histories have not been as accurate as might be desired. In one case in private practice such ulcerations

developed upon the leg, along with well-marked ulcers from the breaking down of gummata, and were carefully watched and studied. After the removal of the dry slough, such ulcers exhibit peculiarities which render it possible to recognize their origin. They bear a resemblance to the round ulcer of the stomach. Malignant precocious syphilides may give rise to similar ulcers, and the tuberculo-gangrenous syphilide of Bazin seems to be closely related to them. Syphilis may furnish adequate cause for direct spontaneous gangrene. It has been satisfactorily shown that in every stage of syphilis the virus exerts its action most constantly on and around the blood-vessels, and we must look particularly to endarteritis if we can exclude other causes of gangrene. As to cerebral arteritis, its great importance has been sufficiently proved, and is none the less so because it is really not a specifically syphilitic process. That it owes its origin to syphilis in a great many cases is generally conceded. Lang, who has paid particular attention to the influence of syphilis on the vascular system, cites a number of instances. There is really no reason why the skin should be exempt from this process, and particularly if arteritis exists in smaller and terminal arteries. Proof will be furnished only when changes in an artery leading to the gangrenous portion of the skin can be shown to exist. This proof the author has not been able to furnish.

The author concludes :

1. Ulcers resembling the so-called gummatous syphilitic ulcer may occasionally result from circumscribed spontaneous gangrene of the skin, without the formation of a previous syphilitic neoplasm.

2. Such ulcers may be distinguished by several peculiarities of formation of floor and shape.

3. They are but little affected, if at all, by antisyphilitic treatment.

4. Spontaneous gangrene in such cases is probably due to endarteritis obliterans.

In the discussion, Dr. Unna, of Hamburg, said that endarteritis obliterans of the smaller vessels in syphilis is now a well-established fact. It is astonishing that in the primary lesions of syphilis we do not have more sloughing than is generally seen.

SECTION IN GENERAL MEDICINE.

Abram B. Arnold, M.D., Baltimore, Md., President.

Secretaries—J. W. Chambers, M.D., Baltimore, Md.; William F. Waugh, M.D., Philadelphia, Pa.

Monday, September 5th—First Day—Afternoon Session.

After calling the meeting to order The President read a paper entitled

AN ADDRESS IN MEDICINE.

He thought it especially appropriate upon such an occasion to review therapeutics and diagnosis.

In reviewing the therapeutic nihilism at one time prevalent, he contrasted it with that over-confidence placed in drugs, which, although similarly irrational, had not been fairly tested.

The treatment of acute febrile diseases were particularly worthy of our study and attention. At present, instead of a uniform there is an English, French, German, and American treatment for fevers. It was interesting to note that within the last three or four decades the rate of mortality in fevers had decreased. As an illustration, it was well to consider the therapeutic treatment of typhoid fever, especially in reducing the fever. All drugs which have been used have had the unfortunate action of overwhelming the system in a manner especially worthy of our attention. The evidence of the value of these remedies has not been established. Hyperpyrexia itself is truly a source of great danger. There is no remedy equal to the judicious abstraction of heat from the body. Those who advocate active treatment ought to review the history of the treatment of pneumonia. The superiority of non-interference over active measures allowed this disease to make the fortune of homœopathy.

Inconsiderate medication is due to an erroneous conception of the true nature of the disease. The general principles formulated by the older physicians were on the whole excellent, so far as the general management of their cases was concerned. They treated expectantly, and were ever on the alert for complications. One part absolutely remedial is good nursing and sound hygienic rules. There is a conservative medicine as well as a conservative surgery.

Preventive medicine, which has been fairly organized, constitutes a new epoch in the history of medicine. Bacteriology and vital statistics teach us valuable lessons. The increased attention to hygiene by the people, the amelioration of the poorer classes by removing young children from the factories, and the diminution of the hours of labor, contribute largely to the increase in the longevity of the race.

Pathology has been advancing, yet therapy not equally so. The practitioner classes his diseases in sclerosis, cirrhosis, etc., with far greater ease than he applies his remedies to them. The text-books have dropped the subjects dropsy, paralysis, etc., and are changing clinical into anatomical diseases. Physicians once thought they had specifics, such as calomel and various alteratives. Perhaps we have too completely thrown them aside.

Symptomatic treatment, however, may not be neglected ; it is often curative. Structural changes also may be modified by remedies which affect the functions of organs.

The criticisms of experimental therapy are untenable, as by this method we arrive directly to a knowledge of the sphere of action of the remedies. Virchow said, "therapy alone tolerates rubbish," a statement not so true now as when he said it. We ought, therefore, not only to know better the therapeutic action of our remedies, but also to increase the number of these agents by experimentation. The numerical method is imperfect, yet is still the best way to compare different methods.

In closing he referred to the difficulties of medical practice, and the necessity of earnestness and a keen insight into physicological medicine.

On motion of Dr. Thomas Hay, of Philadelphia, this paper was referred to the Committee for Publication.

Dr. Ignacio Alvara, of Mexico, read a paper entitled

SOME SUGGESTIONS UPON THE PATHOGENESIS OF YELLOW FEVER.

Although previous pathology ascribes the etiology of yellow fever to a certain microbe, the large experience with the disease in Vera Cruz, Mexico, has led him into the theory that yellow fever is an auto blood-poisoning, either by the acid phosphate of soda of the same blood having been burned from the basic into acid, or by the phospho-glyceric acid set free from the lecythina by the reactions in both cases that have been produced by the living of the microbes upon the constituents of the sanguine fluid.

The idea of yellow fever being a case of poisoning by phosphorus is not a new one. Owing to similarity of the symptoms they were referred to phosphuretted hydrogen. The two etiological factors in yellow fever are, first, fermentation—the one to which the name yellow fever is fitted, and second, the lesions resulting therefrom. Division of this disease is of course artificial, because many of the stages are at times absent. Having taken the abnormal temperature as the basis for the study of the malady, having noted the symptoms that accompany each one of the three stages of the abnormal heat ascent, fastigium, and descent, and by the facts observed, he had arrived at the conclusion that all the cases of yellow fever

must be embraced in two classes: those ending at the fastigium of the abnormal heat, convalescence setting in at once; again, those going on through the descent. The first class includes all cases. Yellow fever has two phases of evolution. The first stage is recovered from, excepting, of course, those cases where the stages are indistinct and run together. The theory was advanced that the first stage of symptoms was caused by an excess of lactic acid in the blood, since poisoning by lactic acid causes aching in the body, dizziness, somnolence, and gastro-intestinal disturbances.

Again, it is inferred that the excess of lactic acid, reacting on the remaining constituents of the blood, produces the acid phosphate (or phosphorus-element), which in turn gives symptoms identical with those of the second stage of yellow fever.

He found eighty-eight per cent. of his cases had characteristic pains in the muscles of the eyes when they were turned upward. Lumbago was present in ninety-five per cent.

In yellow fever there are two conditions, abnormal heat and excessive pathological changes in the blood. This latter condition needs to be investigated by men competent in that department.

Among methods attempted to cure this disease, the doctor mentioned intravenous injection of ether, yet without especially favorable results.

Refused for publication.

Dr. Walter P. Geike, of Ontario, Canada, read a paper entitled

PNEUMONIA AS MET WITH IN VARIOUS PARTS OF THE DOMINION OF CANADA.

Pneumonia he had found to be far more frequently secondary than primary; the former was probably most frequently seen as a complication of typhoid fever. In preparing this paper he had corresponded with physicians practising in newly and sparsely settled countries, and he had found that in these localities, both East and West, it was a rare disease. It never occurred in epidemics. He asks this question, Is it because there are so few inhabitants that there never occurs an epidemic?

As sanitary methods increase low and asthenic forms and epidemics decrease.

In the recent epidemic in Toronto, the disease seemed to affect both the weak and strong alike. Investigation showed that the disease is more acute in rural, and less so in populated districts. There had been cases in the recent epidemic in which it seemed to be contagious. The specific character of the fever would naturally support such a view. Realizing fully the predisposition to the disease which arises from the abuse of alcoholic stimulants, yet improper drainage and water were the great cause.

There was no uniform treatment.

Dr. J. A. Ouchterlony, of Louisville, Ky., reviewed some of the different theories now and formerly held in regard to the local or specific origin of this disease.

Dr. W. J. Scott, of Cleveland, O., said that he found it difficult to reconcile the anatomical changes with any of the advanced hypotheses. He believed it to be infectious.

Dr. J. B. Lester, of Kansas City, Mo., thought pneumonia an infectious disease, sometimes influenced by malaria, by insanitary influences, and at other times by septic conditions. He had cases which did well by immediately instituting the tartar-emetic treatment with a blister. Apparently similar cases this treatment had little effect upon, owing to malarial complications, which rapidly disappear on administration of quinine. Again, the cases of septic origin he treated very successfully with whiskey and milk.

Dr. H. D. Didama, of Syracuse, N. Y., said that the microscope has demonstrated the micrococcus. What has it to do with pneumonia? Is it accidental? Experiments have shown that by inoculation it will produce the disease. In typhoid fever we have many types, yet they all are caused by the same kind of poison. Why could not this be also the case with the different forms of pneumonia? We ought to bear in mind that the latter disease has a regular course. Blisters he approved of in cases complicated with pleurisy.

Dr. James Stewart, of Montreal, Canada, inquired whether pneumonia was more frequent and also more fatal in malarious districts.

Dr. William F. Waugh, of Philadelphia, Pa., thought it difficult for the disease to be infectious in solitudes.

Dr. Theodore H. Boysen, of Egg Harbor, N. J., practised in a district where there was no malaria. Pneumonia in his section was a great rarity.

Dr. Geike replied that pneumonia was not more frequent, but more tedious and of a lower form, when complicated by malaria. It was also more fatal, in so far as it was of a lower form.

The Section then adjourned.

SECTION IN GENERAL SURGERY.

William T. Briggs, M.D., Nashville, Tenn., President.

Secretaries—Dr. Dudley P. Allen, Cleveland, O.; Dr. Karl Mayde, Vienna, Austria; Dr. J. R. Weist, Richmond, Ind.; Dr. Arthur H. Wilson, Boston, Mass.

Monday, September 5th—First Day—Afternoon Session.

The Section was called to order at 3 P.M. by The President, who first welcomed the foreign representatives. He then said that this might be called the age of surgical activity. The whole field is undergoing a complete supervision, and this afternoon session would be devoted to the consideration of

ABDOMINAL SURGERY.

The first paper on this subject was read by Dr. Charles T. Parkes, of Chicago, Ill.

Dr. Parkes stated that the subject of gun-shot wounds of the abdomen had of recent years been more generally understood; that he wished to place in review cases of other gentlemen and those coming under his own experience, so that deductions could be made. Up to 1885 the profession had not looked it in the face; but a few years ago surgeons were opposed to any interference. In 1884 the speaker read a paper upon this subject before the American Medical Association, since which time 36 cases have been reported, recovery taking place in 9 of them, and since coming here he had heard of two more, making 38 reported cases and 11 recoveries. The operation in these cases has been performed under all sorts of surroundings and the cases were not chosen ones. The writer considered that every case should be reported, whether resulting in recovery or death, in order to secure correct statistics.

The diagnosis with the abdomen unopened was at best uncertain, but when to open the future must decide. The writer referred to the cases of Drs. Bull, McEwen, Senn, Hamilton, Dennis, and others already reported. He considered that a gun-shot wound with but one opening would give us hope that the ball might not have passed into the abdominal cavity; the location of the point of entrance and the direction the ball passed, together with weight and distance from which the ball was fired, materially increased the difficulty of diagnosis. The symptoms of shock and hemorrhage were also important factors; also the natural temperament of the patient when in normal health. The writer considered that after an operation had been decided upon the incision should be made in the mesian line, as giving greater access to all parts of the abdominal cavity. If the ball passes up through the diaphragm he considered there was but little to be done. Shock he considered was no

certain indication of perforation having taken place, and that it was a very difficult matter to know when to decline to operate, as many cases that have died have revealed at the post-mortem that the patient could have been saved had an operation been performed. The writer quoted two instances:

Case I.—J. S—— was shot in two places with a thirty-two-calibre ball; he was seen three hours after. One ball went through his body, coming out at his back; he had eaten a hearty dinner just before the shooting. Considerable blood was found in the abdominal cavity, and five perforations were found, one being in the kidney. He seemed to do well for twenty-four hours, but then he died. It was found that death resulted from hemorrhage of the kidney. The speaker considered the kidney should have been removed at the time of the operation.

Case II.—P. J——, aged forty-five, was shot on July 4th. He was seen fourteen hours later, when a large wound was found in the iliac region. Respiration was thoracic, and the abdomen hard and tense. On opening the abdomen, fecal matter was discharged and six inches of gut brought out; the wound was discovered to be very large. After the operation abdominal breathing was resumed. The patient died sixteen hours after the operation; had he been seen earlier the writer thought he would have recovered. He drew attention to the method of treating these wounds, where the mesentery was involved being much more difficult to treat. In these cases he was in the custom of uniting the wound diagonally, commencing the stitches at the mesenteric edge. He had never as yet found it necessary to put in more than one line of stitches, care being taken to draw the peritoneum together. Wounds of the liver should be sewn together with deep sutures. The spleen bleeds freely and is difficult to suture, being so brittle. He thought it might be best to remove it, and this might also be necessary in wounds of the kidney.

The next paper was by Dr. Nicholas Senn, of Milwaukee, Wis., and entitled

AN EXPERIMENTAL CONTRIBUTION TO INTESTINAL SURGERY, WITH SPECIAL REFERENCE TO THE TREATMENT OF INTESTINAL OBSTRUCTION.

Artificial Intestinal Obstruction.—Stenosis.—(*a*) *Partial enterectomy and longitudinal suturing of wound.* Traumatic stenosis from this cause becomes a source of danger from obstruction or perforation in all cases where the lumen of the bowel is reduced more than one-half in size. Longitudinal suturing of wounds on the mesenteric side of the intestine should never be practised, as such a procedure is invariably followed by gangrene and perforation by intercepting the vascular supply to the portion of bowel which corresponds to the mesenteric defect.

(*b*) *Circular constriction of intestine.* The immediate cause of gangrene in circular constriction of a loop of intestine is due to obstruction of the venous circulation, and takes place first at a point most remote from the cause of the obstruction.

2. Flexion.—(*a*) *Flexion produced by partial enterectomy and transverse suturing of wound.* On the convex surface of the bowel a defect an inch in width can be closed by transverse suturing without causing obstruction by flexion. In such cases the stenosis is subsequently corrected by a compensating bulging, or dilatation, of the mesenteric side of the bowel. Closing a wound of such dimensions on the mesenteric side of the bowel by transverse suturing may give rise to intestinal obstruction by flexion, and to gangrene and perforation by seriously impairing the arterial supply to, and venous return from, the portion of bowel corresponding with the mesenteric defect.

(*b*) *Flexion caused by inflammatory and other extrinsic causes* gives rise to intestinal obstruction only in case the functional capacity of the flexed portion of the bowel has been diminished or suspended by the causes which have produced the flexion, or by subsequent causes independently of the flexion.

3. Volvulus.—As in flexion a volvulus gives rise to symptoms of obstruction when the causes which have given rise to a rotation upon its axis of a loop of bowel have at the same time produced an impairment or suspension of peristalsis in the portion of bowel which constitutes the volvulus, or when a diminution or suspension of peristalsis follows in consequence of the rotation.

4. Invagination.—Accumulation of intestinal contents above the seat of invagination is one of the most important factors which prevents spontaneous disinvagination, and which determines gangrene of the intussuscipiens.

Spontaneous reduction is not more frequent in ascending than descending invagination.

The immediate cause of gangrene of the intussuscipiens is obstruction to the return of venous blood by constriction at the neck of the intussuscipiens. Ileo-cæcal invagination, when recent, can frequently be reduced by distentions of the colon and rectum with water, but this method of reduction must be practised with great care and gentleness, as over-distention of the colon and rectum is productive of multiple longitudinal lacerations of the peritoneal coat, an accident which is followed by the gravest consequences.

The competency of the ileo-cæcal valve can only be overcome by over-distention of the cæcum, and is effected by a mechanical separation of the margins of the valve; consequently it is imprudent to attempt treatment of intestinal obstruction beyond the ileo-cæcal valve by injections per rectum.

Enterectomy.—Resection of more than six feet of the small intestine in dogs is uniformly fatal. The cause of death in such cases is always attributable to the immediate effects of the trauma. Resection of more than four feet of the small intestine in dogs is incompatible with normal digestion, absorption, and nutrition, and often results in death from marasmus.

In cases of extensive intestinal resection the remaining portion of the intestinal tract undergoes compensatory hypertrophy, which, macrospically, is shown by thickening of the intestinal coats and increased vascularization.

Physiological Exclusion.—Physiological exclusion of an extensive portion of the intestinal tract does not impair digestion, absorption, and nutrition as seriously as the removal of a similar portion by resection.

Fecal accumulation does not take place in the excluded portion of the intestinal canal.

The excluded portion of the bowel undergoes progressive atrophy.

Circular Enterorrhaphy.—A modification of Jobert's invagination-suture by lining the intussusceptum with a thin, flexible, rubber ring, and the substitution of catgut for silk sutures is preferable to Czerny-Lembert sutures.

The line of suturing on neck of intussuscipiens should be covered by a flap or graft of omentum in all cases of circular resection, as this procedure furnishes an additional protection against perforation.

In circular enterorrhaphy, continuity of the peritoneal surface should be secured where the mesentery is detached by uniting the peritoneum with a fine catgut suture before the bowel is united, as this modification of the ordinary method furnishes better security against perforation on the mesenteric side.

INTESTINAL ANASTOMOSIS

The formation of a fistulous communication between the bowel above and below the seat of obstruction should take the place of resection and circular enterorrhaphy in all cases where it is impossible or impracticable to remove the cause of obstruction, or where the pathological conditions which have given rise to the obstruction do not constitute an intrinsic source of danger. Gastro-enterostomy and jejuno-ileostomy should always be made

by approximation with partially or completely decalcified perforated bone-plates.

In making an intestinal anastomosis for obstructions in the cæcum or colon, the communication above and below the seat of obstruction can be established by apposition with decalcified perforated bone-plates, or by lateral implantation of the ileum into the colon or rectum. An ileo-colostomy, or ileo-rectostomy, by approximation with decalcified perforated bone-plates or lateral implantation, should be done in all cases of irreducible ileo-cæcal invaginations where the local signs do not indicate the existence, or occurrence, of gangrene and perforation. In all cases of threatened gangrene and perforation the invaginated portion should be excised, both ends of the bowel closed, and the continuity of the intestinal canal restored by making an ileo-colostomy by approximation with perforated decalcified bone-plates or by lateral implantation. The restoration of the continuity of the intestinal canal by perforated approximation-plates, or lateral implantation, should be resorted to in all cases where circular enterorrhaphy is impossible on account of the difference in the size of the lumina of the two ends of the bowel.

In cases of multiple gunshot wounds of the intestines involving the lateral, or convex, side of the bowel, the formation of intestinal anastomosis by perforated decalcified bone-plates should be preferred to suturing, as this procedure is equally, if not more, safe and requires less time.

Adhesion Experiments.—Definitive healing of an intestinal wound is only completed after the formation of a network of new vessels in the product of tissue-proliferation from the approximated serous surfaces. Under favorable circumstances quite firm adhesions are formed between the peritoneal surfaces within six to twelve hours which effectually resist the pressure from within outward. Scarification of the peritoneum at the seat of approximation hastens the formation of adhesions and the definitive healing of intestinal wounds.

Omental grafts, from one to two inches in width, and sufficiently long to completely encircle the bowel, retain their vitality, become firmly adherent in from twelve to eighteen hours, and are freely supplied with blood-vessels in from twenty-four to forty-eight hours. Omental transplantation, or omental grafting, should be done in every circular resection, or suturing of large intestinal wounds, as this procedure favors the healing of the visceral wound and furnishes an additional protection against perforation.

The speaker presented some valuable specimens in which the operation had been performed on dogs; these specimens fully illustrated the value of the method advocated, and its entire feasibility, the union in some of these specimens being most remarkable. He called attention to its use in stenosis of the pyloric orifice. The duodenum or the first convenient coil of intestine being connected with the stomach by the method advocated, adhesions would form in from fourteen to twenty-four hours.

The adhesions in the specimens shown were wonderfully firm and strong.

SECTION IN GYNECOLOGY.

Henry O. Marcy, M.D., LL.D., Boston, Mass., President.

Secretaries—Dr. Georges Apostoli, Paris, France; Dr. Ernest W. Cushing, Boston, Mass.; Dr. Horatio R. Bigelow, Washington, D. C.; Dr. Carl Pawleck, Vienna, Austria.

Monday, September 5th—First Day—Afternoon Session.

The President omitted the formal address, and reserved the privilege of a more scientific contribution at a later date. He welcomed the foreign guests in the name of the profession of the entire country, and said that the Executive Committee had spared no effort to make their coming together one of marked pleasure and profit.

It seems, said Dr. Marcy, not invidious to mention the name of Marion Sims, honored by the world, but doubly dear to America, with both pride and sorrow. With pride, because he conferred on our country the honor of being recognized as the birthplace of gynecology; with sorrow, since in the fulness of a ripe manhood he was all too soon taken from us, when we might have hoped his noble presence and eloquent speech would have welcomed you here instead of poor words of mine. May the memory of his gentle presence abide with us, and the earnest spirit with which he sought to know the truth find imitation in our councils.

Dr. Nathan Bozeman, of New York, read a paper, entitled

ARTIFICIAL AND COMBINED DRAINAGE OF THE BLADDER, KIDNEYS, AND UTERUS THROUGH THE VAGINA, WITH AND WITHOUT GRADUATED PRESSURE.

In this paper the author described an instrument which he had devised recently. This draws the uterine away from the mucous membrane, and in the most perfect manner. He has also been able to combine in the same instrument drainage with the dilatation of the cicatricial tissue of the vagina. The form of the instruments which concerns us here is intended for drainage alone, and I have called them intra-vaginal and vulvo-vaginal drainage-supports. The intra-vaginal instrument is applicable in most cases to all positions of the body. The vulvo-vaginal form is suited to the recumbent position, and to cases where the perineum is lacerated. These can be introduced and removed by the patient when necessary. They are small and simple, free from angles and sharp bodies, are readily kept clean, and excite no discomfort or irritation of the vagina. They do not press on the rectum or vagina, nor do they interfere with locomotion.

The author closed his paper with

THE FOLLOWING CONCLUSIONS:

1. The importance of completion of the operation for fistula has not been duly appreciated. This forms, in many cases, the principal difficulty in the successful performance of the operation for the closure of the fistular opening. In other cases, when the fistula is cured, but the complications left without treatment, they lead sooner or later to the death or suffering of the patient. The greatest care should therefore be taken to discover and remove them.

2. Kolpokleisis, occlusion of the os uteri, and incision of the cervix in the bladder or rectum, are unjustifiable operations. They destroy the functions of the generative organs, lead to cystitis, then form venereal and vesicular calculi, pyelitis, and other diseases. Moreover, they are unnecessary. By means of the preparatory treatment of the complication by the aid of my button-suture and my dilating speculum, I have been able to overcome all the difficulties which have been described as indications for operation.

3. The association of combined drainage in the dilatation of the vagina is a great improvement. The inconvenience and evil effects of incontinence of urine are thereby lessened, and the duration of the treatment shortened by the more rapid healing of the incisions and the formation of less cicatricial material in the reparative process.

4. We now propose a means of palliating the suffering due to incontinence of urine in a small proportion of cases of fistula which are incurable by this method—even the dangerous one of kolpokleisis. I believe that some form of drainage may be instituted in every case, and the patient may be thus restored to enjoy life and the performance of its duties.

5. The possession of a system of combined drainage will widen the scope of the operation of kolpo-cystotomy,

done for cystitis, by removing the evils of incontinence of urine, now the chief objection to its performance.

6. Finally, I think the operation which I call kolpo-urethro-cystotomy, followed by the exploration and treatment of the disease of the ureters and pelvis of the kidney, has a brilliant future before it. In the treatment of pyelitis, renal calculi, and obstruction of the ureters, it will restrict within narrow limits the operation of nephrotomy and nephrectomy.

Dr. Grailey Hewett, of London, was called on to open the discussion. He said it gave him great pleasure to take this occasion to visit America and meet those gentlemen whose efforts in the advancement of gynecology had elicited his admiration. The paper just read had shown decided advance in this line of thought. Conservative surgery, in this our day, seems to be running a race with operative surgery. He closed by endorsing the views of the essayist thoroughly.

Dr. Hueston, of Philadelphia, had considerable experience in these cases, which he proceeded to relate.

Dr. Horatio R. Bigelow, of Washington, D. C., read a paper on

CONSERVATIVE GYNECOLOGY.

The paper was divided into the following heads:

1. Plan and purpose of this communication.
2. The conservation of energy in its relation to conservative medicine.
3. What is meant by conservative gynecology?
4. General medicine and its relation to specialism.
5. The tendency to operative measures a dangerous one. Experience gained at a great cost of life. Operations often performed unnecessarily.
6. Conservatism as applied to the treatment of uterine tumors. Recent results from the use of ergot and from the electric current. Exceptionally only do myoma call for laparotomies. The constitutional treatment.
7. Conservatism applied to tubal diseases and inflammations of the ovary. The psychic element. The subjective and objective symptoms. Rest treatment, electricity, Swedish movement, and bathing.
8. The relation of gynecology to the general environment of the patient. Minor disorders magnified into undue prominence by social factors in the every-day life of women. The treatment of such cases.
9. A consideration of oöphorectomy for hysteria, nervousness, and kindred disorders. Seldom warranted.
10. The restriction of abdominal surgery to men competent to practise it.
11. Closing remarks.

Dr W. W. Potter, of Buffalo, N. Y., read a paper on

THE USE OF THE VAGINAL TAMPON IN PELVIC INFLAMMATION.

A married woman, twenty-two years of age, came under the author's care about a year ago, with a previous history of abortion, which happened eight months before, from which time her invalidism dated. Upon his first examination, early in June, he found great tenderness of the intra-pelvic organs and tissues, with partial fixation of the womb. The left tube was enlarged, and presented a banana-shaped mass to the touch, while the surrounding cellular tissue was more or less hard and tense. This finally grew soft, and late in August pus was discharged through the uterus, after which the tube diminished in size. There was relief from pain, and the general health improved. The improvement continued until November, when the tube again grew tender and swollen; but another discharge of pus soon brought relief again. From this time onward the gain was uninterrupted, and she was dismissed cured on April 1, 1887.

The treatment consisted in the regular and systematic tamponnement of the vagina twice a week, copious vaginal lavements of hot water, frequently administered, and constitutional measures, principally of iron and arsenic. The vagina was insufflated just prior to each packing with iodoform, bismuth, mineral earth, or other powder, and then small pledgets of cotton, wool, or jute were introduced in sufficient numbers to make gentle, firm, and even pressure, as well as afford comfortable support. Though there was much more of detail, he said these were the essentials of the management, and their continuous employment for a period of nine months brought recovery.

Reference was made to the advancement gained of late in the differentiation of pelvic diseases of women, whereby the domain of gynecological therapeutics had been so enlarged that it was no longer possible to group all the ailments of woman under the

INEXACT AND MISLEADING HEADS, "ULCERATION," "PROLAPSUS," AND "INFLAMMATION."

One of the important consequences of this more accurate classification of pelvic disease had been to invite surgical aid and interference in regions previously considered unsafe for the knife, and for maladies hitherto regarded incurable. The road to fame was so direct through the open gate-way of a brilliant abdominal section, that it was just possible that some ambitious men had removed an innocent ovary or unoffending tube, now and then, to obtain a "record" as spayers of women. He would not disparage the work of Battey, Tait, Hegar, Goodell, and others in this field, for he believed it of inestimable worth, nor would he deny that excision was often necessary; but, on the other hand, he thought the appendages might often be saved by timely and judicious management. The case reported, one of a number he had seen of a similar nature, was sufficiently typical to illustrate his purpose, and from which the following deductions might fairly be drawn:

1. That many cases of disease of the uterine appendages might be arrested in their progress and diverted to successful issue without operation by appropriate treatment resorted to in their earliest stages.
2. That the early employment of regular, prolonged, and systematic vaginal tamponnement afforded one of the safest, surest, and simplest ways of preventing the ravages, in whole or in part, of the maladies in question, and of averting that mutilating of the sexuality of women consequent upon excision.

VAGINAL TAMPONNEMENT.

This occasion gave him the opportunity of offering some remarks upon the employment of vaginal tamponnement in the treatment of vaginal disease in general, a subject which was again creeping into medical literature through society discussions and papers.

In order to obtain the full benefits of this treatment, it was of the first importance that the packing be well done; that it be so placed as to afford ample support, give secure rest to the parts, make firm pressure, and not become dislodged during its wearing; while, at the same time, it must not produce discomfort, interfere with the functions of the pelvic organs, nor cause irritation in the least degree.

In giving instructions as to its use, he states the tampon must be multiple, and not made up of a single wad or mass, as was too often done.

For the past ten years he has made systematic use of the

KNEE-CHEST POSTURE

in the reduction of pelvic visceral displacements and of the multiple tampon in that connection, while latterly he had also employed them in the treatment of pelvic inflammations, the whole comprising many hundred cases. As a result of this experience he had reached the following conclusions:

1. In retro-deviations of the uterus the reposition of the organ should be made in the genu-pectoral posture without the aid of any other repositor than the finger; it should then be shoved up and held in place by the multiple tampon. This treatment should always precede

the employment of a pessary for a longer or shorter period according to the peculiarities of the case.

2. The foregoing applies with equally cogent force to prolapses and inflammations of the ovaries whenever these principles can be suitably adjusted to such cases.

3. In abrasions, erosions, and ulcerations of the os, in the hyperplastic womb, in subinvolution, in cystocele, in rectocele, and in all conditions of disturbed or impaired nutrition of the pelvic organs, it affords a most efficient form of preparatory or curative treatment, tending to give the organs rest, restore their tone, deplete engorgement, remove blood-stasis, improve locomotive power, and arrest retrograde tendencies in general.

4. In pelvic inflammations, whether of cellular, peritoneal, tubal, or other origin or involvement, it will often change their current or arrest progress, prevent suppuration or abridge its ravages, and thus often guide to a successful issue without a final appeal to a formidable, and perhaps dangerous, operation.

Dr. J. E. Burten, LL.D., of Liverpool, England, read a paper on the subject

WHEN SHALL WE OPERATE IN TUBAL PREGNANCY?

The author considered these operations dangerous to life, more so, perhaps, than ovariotomies, while the diseases for which they are recommended and performed are, as a rule, not so.

The operation is by no means a striking success therapeutically; many of the cases operated on are no better for it, some are even worse, while in good cases it takes at least twelve months for the patient to completely recover from its effects. We hear of "brilliant" cases that have taken two and three years before the "brilliant" results became manifest. It may be fairly assumed most of these would have recovered in that length of time without operation.

When the results are the best possible the woman is mutilated for life, an offence against conservative surgery as well as the first canon of medicine, *non nocere*. The mutilation entailed by the operation is particularly offensive to the sentiments of all civilized nations, and reduces a woman to the position of a female eunuch. Her loss and degradation (?) will certainly be remembered when the recollection of her sufferings has faded.

The objections to the operation being so grave, it ought to be performed only in justifiable cases—after (1) prolonged treatment by less heroic and radical measures; (2) consultation with colleagues; (3) full explanation of the nature of the operation and its results to the patient herself and her nearest friend.

As regards the

OPERATION ITSELF IT IS JUSTIFIABLE

in:

1. Rapidly growing or bleeding myomata after other treatment, patiently carried out, has failed.

2. Pyosalpinx, if life is threatened by repeated attacks of peritonitis.

3. Chronic ovaritis (especially inflammation of the albuginea when Graafian vesicles burst through), when the pain is fixed and constant and months have been spent in unavailing treatment.

4. Parametritis, which, though it may not be dangerous to life at the time, may render the patient a permanent invalid.

5. Cystic degeneration of the ovaries, under the same condition as to pain as No. 4.

6. Neuroses distinctly of ovarian origin that have withstood years of treatment.

The operation is not justifiable in:

1. Myomata, except as noted.

2. Pyosalpinx, if the disease has become quiescent, if pain and fever have subsided and the pus has become inspissated.

3. Hydrosalpinx at any time, unless an associated perimetritis demand removal of the parts. A less radical operation will usually suffice.

4. Perimetritis, unless the disease promises to render the patient a permanent invalid.

5. Ovaritis, except under conditions noted.

6. Cystic degeneration of ovaries, except under conditions noted.

7. Hæmatocele and hæmatosalpinx under any conditions. Laparotomy and drainage may be called for, but removal of the organs, never. The same applies to ectopic gestation.

SECTION IN MEDICAL CLIMATOLOGY AND DEMOGRAPHY.

ALBERT L. GIHON, M.D., U. S. NAVY, PRESIDENT.

Secretaries—Dr. E. Bertheraud, Algiers, Algeria; Dr. Charles Denison, Denver, Col.; Dr. Edmund Owen, London, England; Dr. A. Wernich, Cöslin, Germany.

MONDAY, SEPTEMBER 5TH—FIRST DAY—AFTERNOON SESSION.

The opening address of The President was entitled

ON THE DOMAIN OF CLIMATOLOGY AND DEMOGRAPHY AS DEPENDENCIES OF MEDICINE.

A place was claimed for climatology as one of the sisterhood of medical sciences. The science must be taught in a manner befitting the importance of the subject. Preventive medicine, to which climatology and demography are contributory sciences, is more important than curative medicine. The views of the late Professors Austin Flint and Samuel D. Gross were quoted in support of this assertion.

The climatological study of the future must be based upon more rational methods of investigation. The mere recording of meteorological factors is not sufficient. Determinate climatic characters are not easy to formulate. Malaria is not a climatic disease, because the cause of malaria is a removable one and within the control of man, as proved by the experience in the marshes of Savannah, the lowlands of Holland, the Maremma of Tuscany, and the Roman Campagna, whose poisonous exhalations have been converted into innocuous vapors. The drainage of the Roman marshes has reduced the death-rate of the Italian army to one-third of its former magnitude. There are few specific climatic diseases. Local conditions of insanitation are more responsible for the production of diseases than the general influences of climate. By appropriate regulation of habits, clothing, and diet, the morbific effects of climate may be modified or averted, or its sanitary or therapeutic influence heightened.

The data for future generalizations must be furnished by accurate and laborious collective investigation. Vital statistics must in future be something more than mere records of so many deaths, births, or marriages. Morbility records must form the principal data for the vital statistics of the future. To have these records accurate, voluntary effort cannot be depended upon; they must be made under governmental authority. A rational nomenclature is a necessity, if our vital statistics shall serve as the basis of trustworthy generalizations.

Dr. George H. Rohé, of Baltimore, read a paper upon the

METEOROLOGICAL ELEMENTS OF CLIMATE AND THEIR EFFECTS UPON THE HUMAN ORGANISM.

The writer stated that medical climatology presented a much more complex problem than physical climatology. While the recorded observations of meteorological phenomena must form the basis, other conditions, such as those of the soil, must be taken into account. In studying the most characteristic climatic diseases, such as cholera, yellow fever, and epidemic dysentery, an intermediate factor—namely, the special virus of the disease—must be considered. A hot climate alone will not produce the diseases mentioned.

Sanatory or morbific effects are, however, produced by varying meteorological conditions. The effects of greatly diminished pressure upon the human organism are well known. Paul Bert and others have shown that these effects are not merely due to the physical condition of diminished pressure, but that the relative diminution of oxygen in rarefied air is an important factor in their production. While cases of phthisis usually do well in a moderately rarefied atmosphere, the effects of diminished pressure are not always beneficial, as has been pointed out by Dr. Loomis, who warns against the danger of sending patients with heart disease to high altitudes. It is not probable that diurnal or accidental variations of pressure have any appreciable influence upon health. Investigations conducted by the writer have failed to yield any positive results.

The primary classification of climates into tropical, temperate, and polar indicates the influence ascribed to temperature as a climatic factor. Although recent writers have attributed a determinate climatic influence to humidity, it is probable that this is of far less importance than some have supposed. The temperature must still be regarded as our best index of climate, but too much dependence must not be placed upon it. Many of the unfavorable effects attributed to moisture in the atmosphere ought to be ascribed to coincident insanitary conditions. The sanitary or morbific effects of air-currents have not been sufficiently considered as a climatological factor heretofore.

The tendency among climatologists at present is to deny to ozone any sanitary or disease-producing influence. Hydrogen peroxide is believed to be an antiseptic agent of importance in the atmosphere by some clinicians, who also ascribe therapeutic effects to the aromatic exhalations of certain plants. Very little of a definite character is known of the effects of these conditions. Further investigation is needed. The climatology of the future must be studied upon a broader basis, and ethnological, geographical, and epidemiological data must be taken into account before drawing conclusions.

Dr. W. T. Parker, of Newport, R. I., read a paper on

THE IMPORTANCE OF THE STUDY OF CLIMATOLOGY IN CONNECTION WITH THE SCIENCE OF MEDICINE.

He animadverted upon the prevailing want of knowledge upon climatology among physicians. The science should be more widely studied. A number of health-resorts were mentioned as combining the requisite climatic with the appropriate sanitary conditions to qualify them as resorts for the sick. A wagon-trip across the plains was recommended as one of the best means to obtain the advantages of a climatic health-resort.

SECTION IN MILITARY AND NAVAL SURGERY AND MEDICINE.

Henry Hollingsworth Smith, M.D., LL.D., Philadelphia, Pa., President.

Secretaries—William Browning, M.D., Brooklyn, N. Y.; J. McF. Gaston, M.D., Atlanta, Ga.; Eli A. Wood, M.D., Pittsburg, Pa.

Monday, September 5th—First Day—Afternoon Session.

The President in his inaugural address referred to the greatness of our country, the climatic differences met with over its immense territory, its great extremes of temperature, its geographical characteristics, the large yearly immigration, and the peculiarities, social and physical, which would largely result from these conditions. He drew a graphic picture of the desolation of the alkaline plains of the West, with their inhospitable soil, in comparison with the more favored sections of our country, the fertility of the prairies, and their bountiful flora and fauna.

Referring to the social characteristics of the race, these were largely due, he said, to the struggles and trials of the early settlers, who had a hard time of it in defending the soil reclaimed by great hardships and privations from its aboriginal inhabitants, who were constantly on the war-path against them. The speaker also adverted to the great opportunities that even a man born in the humblest of conditions has of attaining the highest round of the social ladder by energy and perseverance, and gave as examples the lives of some of our presidents. The soldier, he said, also had greater opportunities than in other countries in rising from a simple private to the highest rank, as was so well exemplified by scores of instances during the late war. The wonderful resources of the country in time of emergencies were alluded to, and comparison was drawn between the small regular army of the United States in 1861 to the enormous number of men enlisted up to 1865.

A large majority of these, he said, had returned to peaceful pursuits. The speaker adverted to the remarkable growth of the medical corps of the army, and of the enormous sum of over $47,000,000 having been expended for medical supplies during the late war. He feelingly alluded to the inestimable services of the late Dr. Frank N. Hamilton, of New York, whose recent death was mourned by the nation.

The services rendered by American surgeons in the Crimean, Franco-Prussian, and other European wars were alluded to. The great value of the "Medical and Surgical History of the War of the Rebellion" is admitted, he said, by all Europeans. The speaker then alluded to the great improvements made in the disposition of field hospitals, and to the desirability, which was being recognized, of treating the wounded under canvas, as their chances for recovery and freedom from complications were far greater under these conditions. The importance of selecting the proper site for such hospitals, sheltered from cold winds and naturally drained, was also touched upon.

At the conclusion of the President's address, it was moved that the President be tendered a vote of thanks for his able and interesting address, which was carried unanimously.

The first paper was read by title, and was by Surgeon-Major Francis Patrick Staples, M.K.Q.C.P., Ireland, of the medical staff of Aldershot, England, entitled

A SHORT SCHEME FOR WATER ANALYSIS IN THE FIELD, IN CONNECTION WITH WHICH WILL BE SHOWN A SMALL PORTABLE CASE FOR REAGENTS AND APPARATUS.

Dr. Staples was absent, on account of a death in his family. A few extracts, however, were read in explanation by Dr. Marston, of England.

The second paper of the day, was entitled

ON THE NECESSITY FOR A MORE CAREFUL EXAMINATION OF THE WATER-SUPPLY OF MILITARY POSTS, WHERE AN UNUSUAL AMOUNT OF SICKNESS PREVAILS, AND EXAMINATION OF HYGIENIC SURROUNDINGS,

by Morse K. Taylor, M.D., Major and Surgeon United States Army, of San Antonio, Texas.

The author briefly reviewed the history of army sanitation in this country, and spoke of the alarming death-rate at some of the military posts, due mainly to enteric and malarial fevers; an improvement at these military posts could only be had by giving proper attention to the water-supply and general sanitation of such military posts. The author showed that very little attention had been given to these subjects, and that there had resulted a vast amount of sickness in the army. This sickness is remediable, as typhoid and malarial fevers are preventable; for it is shown that where they exist in excess, it is because of inattention or neglect to seek

their cause and apply the proper remedies. Wherever efforts have been made to supply those military posts and camps with an abundant supply of pure water, there has resulted great improvement in the health of the soldiers and a consequent reduction in the mortality. Many cases were related, reinforced with copious figures, in proof of the author's assertions.

In the brief discussion which followed, Dr. William H. Lloyd, Inspector-General of the British Navy, spoke of the very great importance of an abundant supply of pure water at military posts. He had noticed a certain relation between the rain-fall of a region and the prevalence therein of malarial fevers, and that an increase in the development of these fevers was generally the immediate result of a great fall of rain in the region where these diseases prevail; the speaker was unable to explain the mysterious influence which is here at work. He also, in closing, alluded to the fact that analyses of water for the use of the British Navy are regularly made, and that an improvement in the general health has been directly traceable to the pure water in use therein.

Dr. Joseph R. Smith, U. S. Army, thought it was not an easy thing to decide as to the innocuity and harmfulness of a given water, for it was a well-known fact that many waters, even when containing a large amount of organic substances, could at times be used with impunity, while at others their use was attended with baneful results. It was impracticable, he said, to make use of the microscope in the field; the eyes, nose, and tongue of a soldier were his best guides, he thought, in the selection of water for drinking purposes, but there were times, while in the field, when the soldier could not exercise his judgment in such selection, and must drink any water that can be found, irrespective of its color, smell, or taste, and his drinking such water was not to be prevented. As to the water-supply of military posts, he thought the surgeon was powerless in preventing the pollution of the water, particularly at posts situated within populous districts; but that, in such cases, in public sentiment and appropriate legislation of the several States lay the only remedy.

Dr. Marston, of England, briefly reviewed certain epidemics which he had observed among soldiers, which were undoubtedly caused by the use of impure water; the latter was not the only cause assignable, however, in the development of malarial fevers; the influence of freshly disturbed soil was apt to be overlooked. In certain malarial districts of China this influence was so commonly recognized that it is a popular belief, and one which would seem to be warranted by observation, that even so slight a disturbance as the scratching of the soil by domestic fowls in quest of food is sometimes followed by the occurrence of cases of malarial fever in the neighborhood.

In conclusion, the doctor called attention to the undoubted influence of water containing the salts of lime in solution in the causation of goitre, and gave an illustration of an epidemic observed by him, when the disease was directly traceable to the use of such water.

SECTION IN OBSTETRICS.

. DeLaskie Miller, M.D., Ph.D., Chicago, Ill., President.

Secretaries—W. W. Jaggard, M.D., Chicago, Ill.; Joseph Kucher, M.D., New York, N. Y.; J. Williams, M.D., London, England.

Monday, September 5th—First Day—Afternoon Session.

PRESIDENT'S ADDRESS.

Dr. Miller, in a graceful inaugural address, extended cordial greeting and fraternal welcome to the distinguished guests present, and spoke of his appreciation of the labors of those connected with the Section. The physician's labor was for the good of humanity, and all his achievements and inventions of utility, being generously added to the stock of general knowledge, would be ever preserved, for they became the property of the world. New rules and new applications were constantly arising; yet what rules, new to us, had been ages ago applied. We sought truth along ways beset with difficulties. A symptom might be accepted for a fact in pathology, while nothing was more variable—hence our deductions were liable to prove faulty. Yet no cavity should be too deep to deter us from direct investigation. We should not expect too much, and be not disappointed to find certain questions no nearer solution than they were one hundred years ago.

Sixty thousand obstetricians in the United States were anxiously awaiting true teachings, and our object should be to lead them through their numerous difficulties.

In speaking of certain obstetric difficulties, Dr. Miller hoped that craniotomy in contracted pelves would be but rarely adopted and only in exceptional cases. It was too frequently assumed to be without danger to the mother. The inference from his researches was that the maternal mortality exceeds that reported. Under the new régime the interests of the child became more important. The requisite skill for other operative interference could now be found nearly everywhere.

In ectopic gestation diverse views on treatment prevailed. We have need of more concise rules. He considered early diagnosis of the greatest importance, and then *electricity* to arrest vitality.

While endeavoring to render the puerperal state aseptic, we should not fail to remember the danger from the ordinary agents used, especially where the kidneys were impaired, and he would not employ them in ordinary cases. Cleanliness was a most valuable means of asepsis.

In medicine we tolerated innovation and welcomed progress. We accept that which is fortified by experience and justified by results. The speaker then sketched the history of American obstetrics and obstetricians, beginning at the time of Samuel Guard, the family physician of George Washington, and ending on the verge of our own time.

The address concluded with the mention of those distinguished in the specialty who had died within the past year—Alfred H. McClintock, who in his last address had said, "My thoughts are with the dead;" the genial Alfred Meadows, and Carl Schroeder, one to be emulated, and whose memory should be cherished by all.

A paper sent by J. Braxton Hicks, M.D., F.R.S., of London, England,

ON THE CONTRACTIONS OF THE UTERUS THROUGHOUT PREGNANCY, AND THEIR VALUE IN THE DIAGNOSIS OF PREGNANCY, BOTH NORMAL AND COMPLICATED,

was then read.

Fifteen years ago the author had first directed attention to the fact that the uterus contracted throughout pregnancy at intervals of from five to twenty minutes; since then he had added much to his previous knowledge.

Before the fourth month bimanual palpation was necessary, later external examination was sufficient for its detection. The pregnant uterus was very soft, and offered no appreciable resistance to palpation except during contraction. In a young girl suspected of pregnancy abdominal palpation was often all-sufficient, though internal examination might be necessary. It was of great advantage to obtain decisive proof before making any allusion to pregnancy. A soft condition of the uterus, with a localized lump, often pointed toward the death of the fœtus or to ectopic gestation. The uterus might contract about fibroids. A knowledge of the contractions often rendered easy a diagnosis otherwise difficult, as in ovarian tumor, ovarian tumor and pregnancy, ectopic gestation, and normal gestation, twin

pregnancy, and hydramnios (palpation and the stethoscope as aids). With a dead fœtus the walls might be rigidly contracted. We should always look for corroborative signs.

Several cases were then cited in which the diagnosis was rendered certain only by this sign. The conclusions were:

1. That the uterus contracted at intervals of from five to twenty minutes during the whole of pregnancy, remaining contracted for from three to five minutes.

2. The uterus is firm when contracted, and the fœtus cannot be distinctly felt, though when the uterus is soft the fœtus is easily mapped out.

3. By noticing the contractions we are often enabled to diagnose normal pregnancy from other conditions.

4. The contractions have the physiological use of emptying the uterine veins of the carbonized blood.

5. The carbonized blood probably excites the contractions.

Professor Alexander Simpson, of Edinburgh, Scotland, thought the phenomenon of uterine contraction during pregnancy was now a widely recognized fact. We often met cases requiring all our diagnostic skill, and should employ all known means.

The sign mentioned was especially valuable before the fœtal heart-sounds could be distinguished, and in the third month when it could be employed in addition to Hegar's sign. One important result of these contractions was that when the uterus contracted forcibly, its contained blood was suddenly emptied into the surrounding parts, distending them, and thus favoring the dilatation of the parturient canal.

Dr. A. F. A. King, of Washington, D. C., said there was sometimes difficulty in recognizing the contractions of the uterus, as they might be excited by polypi, by the retention of menstrual fluid, or by fibroids. They were principally of value after the third month. During the first and second months we had no positive means of diagnosis. In single women the diagnosis of pregnancy could not be certainly made by uterine contractions alone. An important point in searching for this sign was to irritate the uterus slightly to make it contract.

Professor Charpentier, of Paris, France, appreciated thoroughly the value of Dr. Hicks' sign, and related a case of hydramnios where its presence made the diagnosis possible.

Duncan C. MacCallum, M.D., M.R.C.S. Eng., of Montreal, Canada, read a paper on

VICARIOUS MENSTRUATION.

After a *résumé* of the literature of the subject and the diverse opinions of modern authorities, the reader cited four cases:

1st. Mrs. W——, aged thirty-eight; six children. Never nursed. Good health. Two months after birth of child had molimina and vomited blood. Treated by rest, ice, and gallic acid. No unpleasant after-effects and no further hemorrhage for four weeks, when she again had molimina, followed by hæmatemesis. At next period the menses reappeared and have been normal since. Continued good health.

2d. Healthy woman; single. On the first day of a menstrual period was exposed to cold, and menses stopped; next day vomited blood; no vaginal discharge; regular since and healthy.

3d. Patient, aged thirty-three; healthy. First menstruation at fourteen years of age. Soon after had scarlatina, followed by amenorrhœa until eighteen. At twenty-three menstruation became very scanty and was accompanied by epistaxis for six periods, when it became regular again. Recently has again become scant and is accompanied by the epistaxis as before.

4th. Healthy woman. Pregnant three months. Six weeks before had received a severe fright. Had a profuse hæmoptysis on two successive mornings, and three days later aborted. Four weeks later molimina and hæmoptysis, but since normal menstruation. Chest perfectly sound; good health. In this case the ovum was killed six weeks before ovulation became established, and obstruction being offered to the usual flow, hemorrhage took place from the weakest point.

To constitute vicarious menstruation there must be (*a*) absence of menstrual blood-flow, (*b*) blood from some other organ than the uterus, and (*c*) no other assignable cause for the hemorrhage than the increased premenstrual blood-tension.

A hemorrhage under these conditions is truly supplementary and clearly vicarious.

Dr. Charles T. Parks, of Chicago, Ill., mentioned a case occurring in a single woman, twenty-three years of age, sick eighteen months. For four months defecation had been at intervals of from one to seven weeks, and during this time only one ounce of urine had been passed daily. Severe fæcal vomiting. No normal menstruation for two months, but at the time for the periods molimina and vomiting of pure blood. Patient was a physical and mental wreck. Exploratory abdominal incision showed intestines filled with scybalæ. The ovaries, much enlarged, were removed. Urine at once increased to a pint daily, many scybalæ were passed, and general health rapidly improved. For two periods the patient had molimina and spat blood. Heart and lungs normal.

Dr. Opie, of Baltimore, Md., thought cases of vicarious menstruation rare and illy defined. He believed that when the menstrual flow was impeded the vascular tension would seek relief at the weakest point.

Dr. Nelson, of Chicago, Ill., recalled a case where bleeding from rectal hemorrhoids occurred at menstrual periods, there being no uterine flow. The piles being cured and the cervix dilated, the menses appeared and gradually became normal.

Dr. Rodney Glissan, of Portland, Ore., in thirty-nine years had seen three cases: in one, menstruation had been regular, but after a serious illness hæmoptysis appeared every month and no vaginal flow for a year, when menstruation again became regular and the cough ceased. Now healthy.

Professor T. Lazarewitch, M.D., of St. Petersburg, Russia, presented a paper on

THE MECHANISM OF LABOR AND THE NORMAL FORCEPS.

After calling attention to the factors concerned in the mechanism of labor, and the necessity of an accurate knowledge of the mechanics of the process, he described a forceps which he had devised, having straight parallel blades, and locking with a simple tenon and screw.

His conclusions were: 1. That forceps be considered as a continuation of the hand as feelers.

2. That the less the dimensions of the blades the better they could be guided.

3. That detrimental action increases with the size of the blades.

4. Convex margins should not be so thin as to cut, or so thick as to obstruct.

5. That the instrument should lock easily, but allow slight longitudinal rotation of the blades.

6. Blades should be parallel.

7. Handles designed for convenience in guiding and the avoidance of injurious pressure.

8. Should be of smooth metal, so as to be easily made aseptic.

9. That the pelvic curve was injudicious, detrimental, and difficult to employ.

10. That his parallel normal forceps filled all these conditions.

W. S. Stewart, M.D., of Philadelphia, Pa., exhibited an

IMPROVED FORCEPS WITH PARALLEL BRANCHES.

The advantages claimed are: 1. That either blade may be applied first. 2. The impossibility of its slipping

when properly applied. 3. Moderate and even compression, the degree of compression being regulated by the amount of resistance. 4. Great facility for making traction.

Dr. Opie thought that most forceps had merit in proportion to the skill and familiarity in their use by the individual operator. It was not so much the instrument as the man. We should not try to do by mechanism what the skilful hand may execute. A properly educated touch and hand were the best means of warding off dangers incident to the use of the forceps. He believed in the use of a moderate pelvic curve.

SECTION IN OTOLOGY.

S. J. Jones, M.D., LL.D., Chicago, Ill., President.

Secretary—S. O. Richey, M.D., Washington, D. C.

Monday, September 5th—First Day—Afternoon Session.

The President gave a brief history of the progress of otology during the last twenty-five years, its present state, and its relations to general medicine.

Dr. S. S. Bishop, of Chicago, Ill., read a paper entitled

REPORT ON 5,700 CASES OF EAR DISEASE, CLASSIFIED BY AGE, SEX, OCCUPATION, AND DISEASE; CAUSATION.

His conclusions were:

1. Youth is a predisposing cause; more than one-fourth of the whole number of cases were under fifteen years of age.

2. Sex does not figure in the etiology of ear diseases.

3. About eighty per cent. were chronic diseases, and about ninety per cent. were diseases of the middle ear.

4. The causes of naso-pharyngeal catarrh are the proximate causes of middle-ear disease.

5. The nervous temperament was predominant.

Dr. B. Loewenberg, of Paris, France, read a paper on

THE TREATMENT AND THE BACTERIOLOGY OF AURAL FURUNCLES.

In 1880 and 1881 I published the results of my researches on the practical nature of aural furuncles, together with the theoretical and practical applications, the substance of which can be given as follows:

1. Boils are caused by an affection from outward, viz., through the ducts of the cutaneous follicles.

2. The successive outbreak of furuncles on the same individual takes place by auto-contagion, that is, through transport of the cocci upon the skin.

3. Infection from one person to others is possible, and originates from the same process as in No. 2.

These fundamental points have led me to a plan of treatment for boils and for furunculosis in general. I shall now expose this method with regard to the furuncles of the external ear, together with the results hitherto obtained.

My course of treatment is about the same as the one formerly proposed by me for otorrhœa, that is, the use of an over-saturated solution of one part of extremely fine powder of boracic acid to five parts of strong, even absolute, alcohol. This compound I use in instillations into the meatus, to be repeated three to four times a day.

As long as the boil is not yet opened a simple saturated alcoholic solution of boracic acid is sufficient, but when pus is already discharging I prefer the over-saturated solution, as it deposes a certain amount of boracic powder, dissolving gradually in the pus and thus exercising a continual anti-bacterial action.

Alcohol, besides its efficaciousness against micro-organisms, is, moreover, destined to facilitate the penetration of the compound into the ducts of the follicles, the seat of the disease. The fatty lining and contents of these capillary canals oppose, according to physico-chemical laws, a resistance to the entering of watery liquids, while alcohol, according to its affinity to fats, easily penetrates.

Incision of boils certainly sometimes facilitates this course of treatment, but it is often very difficult to practise it just so as to divide the follicle-ducts, which seems to me the desideratum.

Cocaine, though applied upon the epidermis, often procures passing relief.

RESULTS.

An early application of the saturated solution of boracic acid in strong alcohol often arrests the boils; even in the cases where this abortive treatment should fail, the perseverant use of the over-saturated solution always stops the otherwise nearly unavoidable succession of boils, originated by auto-contagion, as I have called it (*loc. cit.*). These results seem to me of great importance, firstly, because aural furuncles are known to be extremely painful; secondly, because, according to my experience, the longer this local furunculosis lasts the greater is the tendency of the boils to form in parts situated nearer and nearer the drum, and consequently to prove more and more painful. These results, to the best of my knowledge, have not been obtained before my researches.

Many female patients suffer, often for years, from aural boils arising before or during each menstrual period, a fact an explanative theory of which will be found in my paper. In such cases my treatment arrests these boils, or, at least, prevents their return. Nay, their formation may even be successfully prevented by a prophylatic use of this treatment begun before the catamenial epoch.

The same results can be obtained with persons who are regularly attacked by this affection in spring or fall.

BACTERIA IN EAR-FURUNCLES.

I have undertaken bacteriological researches in a certain number of cases of still unopened boils of the meatus. In each case I first syringed this canal and then filled it for ten minutes with a lukewarm solution of bichloride of mercury ($\frac{1}{2000}$). A small parcel of the pus was inoculated into agar-agar or nutrient gelatine and plate cultivations were made of the whole.

I obtained the following results: The micro-organism most frequently found was staphylococcus albus, which was absent in only one case, then came staphylococcus aureus and sometimes staphylococcus citreus. Only in one case all these three staphylococci were traced together.

These results differ from those obtained by my friend N. Kirchner, from Würzburg, who only found staphylococcus albus.

Dr. L. Turnbull, of Philadelphia, Pa., followed with a paper on

THE CAUSE AND TREATMENT OF AURAL FURUNCLES.

These papers were fully discussed by both foreign and home representatives.

SECTION IN PATHOLOGY.

Alonzo B. Palmer, M.D., LL.D., Ann Arbor, Mich., President.

Secretaries—Dr. H. M. Biggs, New York; Dr. Isaac N. Hines, Cleveland, O.

Monday, September 5th—First Day—Afternoon Session.

The President, in his inaugural address, discussed the progress of medicine toward exact science. Remarks on the address were made by Dr. Isaac N. Quimby, of Jersey City, N. J., and Dr. E. P. Allen, of Pennsylvania.

Dr. George R. Elliott, of New York, N. Y., read a paper with the title,

PRESSURE PARALYSIS OF POTT'S DISEASE,

in which he reported a case and presented the specimen showing pressure of the cauda equina, accompanied by secondary ascending degeneration of the posterior columns of the spinal cord.

The author's conclusions were based upon (1) experimental physiology; (2) pathological findings; and (3) clinical manifestations. They demonstrated that the lesion is a mechanical one in the majority of cases, and not a true myelitis, as ordinarily described—the latter being the lesion in only a small number of cases. They further demonstrated how circulation is interfered with and how such interference leads to the production of many forms of the paralysis recognized clinically. The specimen was interesting in showing the compression lesion of the cauda equina, and as probably being the first case reported where the pressure of the cauda equina, leading to secondary degeneration, was due to spinal caries.

Diagrams were used to illustrate the points made.

SECTION IN PSYCHOLOGICAL MEDICINE AND NERVOUS DISEASES.

Judson B. Andrews, M.D., Buffalo, N. Y., President.

Secretaries—G. A. Blumer, M.D., Utica, N. Y.; M. le Dr. A. Bouchereau, Paris, France; E. D. Ferguson, M.D., Troy, N. Y.

Monday, September 5th—First Day—Afternoon Session.

The Section was called to order by Dr. Andrews, Superintendent of the Buffalo Insane Asylum. After the reading of the list of Vice-Presidents and Secretaries, the President delivered his address, entitled,

THE DISTRIBUTION AND CARE OF THE INSANE IN THE UNITED STATES.

After delivering an eloquent eulogy on Dr. John P. Gray, who was the first President of this Section, he said: The amount of insanity bears a close relation to the duration of the social and governmental life of the people. Dividing the country into two great belts of North and South, there is an almost regular proportionate decrease of lunacy as we leave the older settled parts of the country along the Atlantic coast, till we reach the extreme Western slope.

The New England States lead with one insane person to every 359 inhabitants. This decreases until we reach the newer States and Territories with one insane person to every 1,263 inhabitants. In the seaboard States of the Southern belt we have one to every 610 inhabitants, and the extreme Southern States with but one to every 935 of the population. This emphasizes the statement that the pioneers of our newer settlements are the more hardy and vigorous citizens, and that the feeble and dependent are left in their former homes to enjoy the comforts of the hospitals and asylums, which are the special growth of the older civilization.

New York is the first Irish city in the world, and Berlin and Hamburg are the only cities which contain as many Germans as our own metropolis. We have among the negroes in the United States 1 insane person to every 1,097. In the negro race the proportionate increase of insanity is far greater than in any other division of the population. From 1870 to 1880 there was an increase in the census of the colored race of 34.85 per cent., while for the same period there was an increase of 25.8 per cent. of the insane. This large multiplication has occurred since emancipation from slavery, and through the consequent change in condition and life. The causes are briefly told—enlarged freedom, too often ending in license; excessive use of stimulants; excitement of the emotions, already unduly developed; the unaccustomed strife for means of subsistence, educational strain, and poverty. Among the Chinese and aborigines there has been but a small increase of insanity. There is among them less of the refinements of civilization, less competition and struggle for place, power, or wealth, and, as a consequence, less tendency to mental deterioration.

Dr. Andrews presented a list of State institutions in the United States, number of patients in each, and also the number of medical officers attached to each institution. One hundred and twenty-one asylums were represented, fifteen of these having been built since 1880. In 1880 there were 39,093 patients in these asylums. In 1886 the number had increased to 61,411, an annual increase of nine per cent. At the present rate of increase, before the end of the decennial period we shall have 75,000 in our asylums.

Dr. Andrews next referred to the diversity in lunacy laws in the various States of the Union, comparing them with the general governmental laws of Great Britain. Special accommodation for the criminal class, a highly desirable innovation, has been entered upon by two States only—New York and Illinois.

With the exception of Delaware and Vermont, every State in the Union has adopted the State system of caring for the insane, and New York was the first State to erect separate asylums for the chronic insane. Asylum architecture has undergone material changes during the past twenty years, the plan now most generally adopted being that of building detached blocks of structures in different parts of the asylum grounds, within easy reach of the administration building, these to accommodate the feeble and helpless, the epileptics and acutely maniacal patients. In many portions of the country, buildings separate and complete are joined by connecting fireproof corridors.

The President next outlined some of the important changes occurring in the interior management of asylums at the present time. Among them, the introduction of electricity for lighting purposes, of direct radiation for heating purposes, and of natural ventilation as taking the place of the blower-fans much in vogue in former years.

A higher medical standard is to be noted in the asylums of the United States. The medical officers are in very few cases appointed through political favoritism, and in the State of New York the Civil Service requirements insure the sound medical equipment of assistant physicians. Oöphorectomy is now recognized as a legitimate mode of treatment, and castration in appropriate cases has, at present, some able advocates; electricity is now being used with more intelligent knowledge of its power. Its handmaid massage, less powerful and less mysterious, but not less practical, has gained a position of prominence in the treatment of insanity in many institutions. The experiments in mesmerism, mind-reading, and the faith-cure have led to a closer investigation into the relation between mind and body, with a result of finding in expectant attention a valuable and legitimate help in the treatment of mental diseases.

D. Hack Tuke, M.D., F.R.C.P., London, Eng., sent a paper, which in his absence was read by Dr. G. F. Blandford.

THE VARIOUS MODES OF PROVIDING FOR THE INSANE AND IDIOTS IN THE UNITED STATES AND GREAT BRITAIN, AND ON THE "RAPPROCHEMENT" BETWEEN AMERICAN AND BRITISH ALIENISTS IN REGARD TO THE EMPLOYMENT OF MECHANICAL RESTRAINT.

It was largely a comparison of the systems pursued in both countries. At the last official census there were 80,000 idiots and insane in England and Wales, 72,000 of them being paupers and 8,000 belonging to the private class. In the workhouses of England fourteen per cent. of the paupers were cared for, and Dr. Tuke believed well cared for. In some of the workhouses there

are very good lunacy wards, and these, in his opinion, provided far better for this class than do American almshouses. The doctor thought well of the increasing tendency in this country to segregate the insane as shown at Willard and Kankakee. He deplored the fact that so many patients were still retained in the almshouses of the United States, and instanced the abuses in the Cook County Asylum at Chicago. The doctor thought the plan now being adopted in Massachusetts of boarding the chronic insane in private families was attended with considerable danger to the families, and might also result in overcrowding of patients, but, as a whole, commended the new departure.

Dr. Tuke concluded with remarks upon the little difference at present existing in the practice of British and American alienists, as regards non-restraint. He said that the system of Conollyism or strict non-restraint was not a feasible one in either country, and was glad to know that in the United States judgment had been used in the use or non-use of restraint, instead of blindly clinging to an ideal.

Dr. Tuke's paper was discussed by Drs. Savage and Andrews.

Dr. Savage, of London, Eng., said that he was glad to know that enlightened American superintendents had not tried to carry out the principles of strict Conollyism. There could be no absolute non-restraint so long as asylums existed, because life in an asylum in itself meant restraint. It was a mere matter of degree. The humane treatment of insane patients was in direct relationship to the civilization of a country. Let the principles of non-restraint be preached at all times, and let your attendants know this; otherwise you will have trouble. Youthful alienists might preach the doctrine of Conollyism pure and simple, but so high an ideal could not be attained so long as the preservation of society and the preservation of the patient's life are to be considered.

Dr. Andrews said the practice of American alienists was for the minimum of restraint in all cases. In former years there had been in the minds of Americans a misconception of the real practice of their English brethren. A study of the Blue Books, however, had served to show that strict non-restraint—Conollyism—had not been carried out in Great Britain. There had been considerable feeling manifested in the past between English and American mental specialists upon this topic, and Dr. Andrews was glad to say that as a more perfect understanding had come in regard to English practice, there was found to be little actual cause for dispute or disagreement.

The last paper of the day was read by Dr. Henry M. Hurd, of Pontiac, Mich., on

THE RELIGIOUS DELUSIONS OF THE INSANE.

He first treated of the religious delusions which accompany the mental development of over-stimulated and injudiciously educated children. These delusions are apt to take the form of morbid fear. When the child fails to derive pleasure and an emotional glow from prayer or praise, he fancies that some duty has been neglected or improperly performed, and is tormented by doubts and overwhelmed by remorse. An interesting case was then given by Dr. Hurd. The next class treated of by the author of this paper were patients suffering from the religious delusions of the insanity of masturbation. In the beginning morbid fear is predominant, and a study of the Bible and a habit of introspection is present. The patient is scrupulous in all religious observances, and there is a silly vanity in religious matters. Hallucinations are present. The patient becomes egotistical in his religious ideas. Dr. Hurd gave an illustrative case of this form of mental disorder. The patient had striking hallucinations of hearing and constantly communicated with invisible persons. The doctor next passed to the religious delusions of paranoia. In the congenitally abnormal class referred to there is, as early as puberty, a precocious sexual excitability which gives rise to an unnatural religious susceptibility. The patients have a strong religious bias and are apt to embrace peculiar views, or to be attracted by the latest novelty in religion. The immediate cause of the development of religious delusions is generally some physical ailment or shock. One patient, after praying for several nights in a corn-field, in great agony of mind, felt the burden of sin fall from his aching shoulders and saw it glide away in the darkness, dark, sinister, and, to use his own expression, "like a small woodchuck." Dr. Hurd cited many interesting cases, taken from the records of his asylum, as illustrative of this form of mental disease.

The doctor said the connection between sexual impulses and the development of religious delusions was not from any association of ideas, but rather from the close association and inherent unity of emotional states. The religious delusions of over-stimulated children are generally relieved by rest, freedom from study, and a judicious correction of the educational errors which produced them.

SECTION IN THERAPEUTICS AND MATERIA MEDICA.

Traill Green, M.D., Easton, Pa., President.

Secretaries—Dr. Frank Woodbury, Philadelphia, Pa.; Dr. Alfred S. Gubb, London, England; Dr. L. Lewin, Berlin, Germany; Dr. F. Dronke, Berlin, Germany.

Monday, September 5th—First Day—Afternoon Session.

Among those in attendance at the opening of the Section were Drs. Edmonston Charles, Middlesex, England; J. G. S. Coghill, Isle of Wight, England; William Murrell, London, England; Charles D. F. Phillips, London, England; Ralph Stockman, Edinburgh, Scotland; T. Gnezda, Berlin; Albert Fricke, Philadelphia, Pa.; F. E. Stewart, Wilmington, Del.; Alfred D. Gubb, London, England (French Secretary of Section); and J. M. Carter, Waukegan, Ill.

The President delivered a brief address at the opening of the session, which dealt chiefly with the history of the development of the study of therapeutics and materia medica, especially referring to the labors of Dr. John Morgan, of Philadelphia, who delivered the first lectures upon the subject in this country. The instruction which he gave was based upon the teachings of the University of Edinburgh, and its traditions have largely influenced medical education in this country.

Dr. Phillips, of Ventnor, Isle of Wight, Vice-President of the Section, occupied the chair during the opening address, and at its conclusion returned thanks for the interesting remarks, and said that English therapeutists felt under great obligations to Wood, Dunglison, Stillé, and other American workers in this field. He referred to his recent labors upon the subject of the action of diuretics, the results of which he had embodied in a paper which he is shortly to read before this Section.

Dr. J. M. Carter, of Waukegan, Ill., presented a

SYNOPSIS OF THE MEDICAL BOTANY OF THE UNITED STATES,

in which 140 orders, 620 genera, and over 1,300 species are described. The study of these is much simplified by the knowledge that the different species of the same plant resemble each other in therapeutic effect, differing principally in degree. There are similar differences in the same species, according to the conditions under which the plants are grown. Vogel has pointed out that *conine* does not appear in conium plants grown in Scotland; cinchona plants grown in hot-houses do not produce quinine. The mistletoe and the black haw he considered the most valuable additions recently made to our therapeutics, the former in urethral, the latter for uterine, irritation.

Dr. Coghill had been much impressed by the value of some American indigenous drugs, but he pointed out

the necessity of better appreciation of their physiological effects in order to ascertain their real value in therapeutics.

Dr. Phillips said that with reference to one drug mentioned, grindelia, he had obtained excellent results, and had a long series of notes of its successful use in asthma and emphysema with dilated heart.

Dr. William Murrell, of London, had noticed a great variation in the strength of drug preparations; as the rule, the samples sent for trial were made with more care than the ordinary article supplied on prescription.

Dr. Frank Woodbury, of Philadelphia, mentioned the employment of mistletoe in weak heart, and in post-partum hemorrhage, owing to its effect upon unstriped muscular tissue. Rhamnus Purshiana he considered a useful substitute for rhubarb, and equally efficient as a cholagogue.

Dr. F. E. Steward, of Wilmington, Del., read a paper entitled,

A PROPOSED INVESTIGATION OF THE MATERIA MEDICA OF THE WORLD BY THE GOVERNMENT OF THE UNITED STATES,

in which he advocated governmental supervision over novel therapeutic agents, and the placing of some restraint over the commercial enterprise of drug manufacturers, who introduced new drugs at extortionate prices. He also denounced the proprietary medicine business as an abuse of the copyright privilege. He suggested the establishment of a bureau for the examination of proposed new remedies, proprietary or otherwise, by the government, and to include a supervision over the entire drug-supply of the country.

Dr. H. H. Rusby, by invitation, opened the discussion. He considered the present a very opportune moment for agitating such a measure as the paper advocated. By a combined effort of the physicians and pharmacists, a committee might be appointed to improve the botanical work done under the direction of the United States Government. Hitherto, the amount appropriated had been lamentably inefficient, and had been carried on under the Department of Geology; it should be transferred to the Department of Agriculture. If the International Medical Congress were to pass a resolution, calling upon Congress to give adequate means and energy to the botanical work, its value would be greatly enhanced, and its importance in a medical point of view would be very great.

Some remarks were made by different members, denouncing the patent medicine abuse in this country.

Dr. Steward, on closing the discussion, said that a patent was never intended to secure unlimited secrecy, but on the contrary, to insure publication of an invention after a period of time. Moreover, the so called patent medicines are not patented, and cannot be patented; they are sold under a misapplication of the copyright law.

SECTION IN LARYNGOLOGY.

William H. Daly, M.D., Pittsburg, Pa., President.

Secretaries—William Porter, M.D., St. Louis, Mo.; D. N. Rankin, M.D., Alleghany, Pa.; Dr. Ottakar Chiari, Vienna; Dr. Hermann Krause, Berlin, Germany; Dr. E. G. Moure, Bordeaux, France.

Monday, September 5th—First Day—Afternoon Session.

The Section was formally opened at 3 P.M. with

THE INAUGURAL ADDRESS OF THE PRESIDENT.

It was most gratifying, he said, to see so many gathered together from all parts of the Union to welcome our guests who have come from afar, and to redeem the pledge made for them at Copenhagen in 1884. It was moreover a source of the highest pleasure to meet so many of those from foreign lands, whose names are far too familiar to admit of their being regarded as new acquaintances. We appreciate the honor of entertaining such representative men, and extend to them our heartfelt greeting, and cordial welcome to all.

The President then called attention to the status of laryngology in 1876, compared with its present advancement. In rhinology much has been done for the successful treatment of hay fever since the appearance of a paper by the President, in 1881, upon the predisposing intra-nasal causes of this disease. Now a large percentage of those who formerly fled to the mountain-tops in search of relief may be cured at home by proper and rational surgical treatment. The lamented Hack and other able workers claimed more from this plan of treatment than he then advised; but seven years of observation strengthen his belief that a large proportion depend upon a chronic intra-nasal disease, without the presence of which pollen, dust, and other agents are innocuous. A hope for the future is that more perfect local treatment may cure a still larger percentage.

The laryngologist of the future must give more attention to the nasal passages, and the rhinologist must be more of a surgeon than a physician. Who has not noted the rapid improvement of puny children following the treatment of enlarged tonsils and hypertrophied turbinated tissues, so as to give free breathing space? Many have with him verified by years of experience that a large proportion of inflammatory diseases of the larynx are secondary to intra-nasal diseases of a like character. The aid that modern rhinology extends toward the treatment of diseases of the internal and middle ear is appreciated by every aurist.

The President called attention to our indebtedness to the persevering work and ability of the now silent members, such as the late Elsberg, Krishaber, Foulis, Bruns, Waldenburg, Burow, Böcker, and Hack. In closing his address the President made the announcement that Dr. Morell Mackenzie was about to receive knighthood from the Queen. A motion was carried that suitable congratulations should be forwarded.

The first paper was read by Dr. Richard H. Thomas, of Baltimore, entitled

A CONTRIBUTION TO THE CAUSES OF SO-CALLED HAY FEVER, NASAL ASTHMA, AND ALLIED AFFECTIONS; CONSIDERED FROM A CLINICAL STANDPOINT.

The term hay fever he uses, not because scientifically correct, but because it is well understood and convenient. The factors that appear to enter into the causation of hay-fever and other nasal neuroses are:

1. The general nervous system. Although a neurasthenic condition is so often present with a nasal neurosis, the frequency of its occurrence, without reflex phenomena associated with the upper air-passages, shows it inadequate to explain the phenomena.

2. The theory that the condition of the nervous system is similar to epilepsy has not been proved.

3. The intra-nasal condition is usually that of hypertrophy, or such disease as polypi, deflected septum, etc., tending to more or less nasal obstruction.

The author has noted, however (*a*) that nasal obstruction in most cases is not associated with reflex phenomena, and even in neurasthenic individuals, as Dr. Bosworth, of New York, claims, only the "proper pollen" is needed to produce hay fever. One unique case improved as occlusion advanced. (*b*) Obstruction is not the first symptom in asthmatic manifestations, nor is it always present. (*c*) Cases have been reported of reflex phenomena associated with atrophic rhinitis. Morell Mackenzie has seen cases where there was nothing abnormal beyond hyperæmia, and author corroborates as far as nasal asthma is concerned. (*d*) Temporary attacks are brought on by touching sensitive areas, independent of nasal obstruction.

4. The author has seen cases where hay asthma followed chronic nasal trouble, and other cases where it

apparently preceded structural change. Special sensitive areas are claimed to exist in the upper air-passages. Irritation, disease, hypertrophy, polyp, etc., give rise to reflex phenomena. They are variously located by different authors, on the septum and turbinated bodies. When all are considered, there is very little mucous membrane that is not included.

5. After experimenting, Dr. Thomas concluded that the sensitive areas varied greatly with different individuals. Examinations were made between the attacks. Sensitive areas on one side at times bear no relation to those on the other. He could not decide which portion of the nasal tract was most sensitive, unless it was the septum. The favorite location is that part supplied by the olfactory. Phenomena noted were paroxysmal sneezing, or cough, and temporary asthmatic dyspnœa, headache, etc. ; none where the mucosa was healthy.

Reflex sensitive areas are found in hay fever but not in the normal nose.

6. Modern research shows that the nervous element enters to a large extent. A peculiar condition either of nerve-centres or endings gives perverted action under certain forms of irritation. He agrees with Lublinski that the olfactory, trigeminus, and sympathetic are involved in producing a paroyxsm. No such disturbance is caused by pathological conditions until an exciting cause is present.

Exciting causes.—(1) Inert substances floating in air, dust, pollen, etc. ; (2) psychical impressions ; (3) meteorological changes, sunlight, wind, etc. ; (4) morbid changes or growths ; (5) irritation reflected from distant parts of the body.

Any of these may give rise to a paroxysm when idiosyncrasy exists, not otherwise.

Pollen of Indian-corn, ragweed, luxuriant vegetation, smell of flowers, flour, meal, dust, odors of close room, where oysters have been opened, dissecting-room, dust of tobacco, smoke, etc.

Mental impression and often sympathy with another who is afflicted will cause an attack.

Hereditary tendency is often noted. What affects one may have no effect on another.

Treatment.—Remove patient from irritant or irritant from patient if internal, as when polyp, etc. Irritation of distant organs should be treated. It is often difficult to account for the curative effect of change of locality.

Use of cocaine gives temporary relief, but there is danger to tissues from protracted use. Powders are of doubtful benefit. Flannels give some relief. Radical treatment is called for. If nervous tissues are at fault treat accordingly. Iron, quinine, arsenic, hydrobromic acid (Gardiner's syrup), valerianate of zinc, etc., build up health. We are indebted to Dr. Daly for the introduction of local treatment of hay fever. Cure co-existing nasal disease and cauterize sensitive areas. The galvanocautery is preferable to acetic or chromic acid. Avoid destroying too much tissue. Prevent pain by cocaine and follow up with Dobell's solution. Carry on treatment between attacks and leave no sensitive areas untreated. Each patient requires separate study.

SECTION ON PHYSIOLOGY.

JOHN H. CALLENDER, M.D., NASHVILLE, TENN., PRESIDENT.

Secretaries—R. W. Bishop, M.D., Chicago, Ill. ; Bernard Fraenkel, M.D., Berlin, Germany ; Randolph Barksdale, M.D., Petersburg, Va.

MONDAY, SEPTEMBER 5TH—FIRST DAY—AFTERNOON SESSION.

In his inaugural address THE PRESIDENT directed special attention to the influence exerted by the cell on the processes of development and decay.

DR. DANIEL G. CLARK, of Toronto, Canada, read a paper on

THE BASAL GANGLIA OF THE BRAIN AS CENTRES OF PSYCHIC AND FUNCTIONAL POWER.

The author of the paper maintained that these ganglia are psychical centres : (1) Because of their greater activity physiologically ; (2) because they are the focal centres to the hemispheres ; (3) they are vital points of greater significance than any other part of the brain, and (4) experiments point to their directing and controlling power.

The paper gave rise to discussion which was participated in by Drs. Love, Wythe ; Stockman, of Edinburgh ; Kleinschmidt, of Washington ; Halliburton ; Professor Madden, and Dr. Boenning, of Philadelphia.

DR. RICHARD CATON, of Liverpool, England, then read a paper entitled

RESEARCHES ON ELECTRICAL PHENOMENA OF CEREBRAL GRAY MATTER.

These were the chief results obtained. Owing to the great difficulty of the investigation, more than half of the experiments were valueless.

1. Electrical currents are present in the gray matter of the convolutions.

2. These currents are increased during the arrest of functional activity caused by anæsthetics or death. After death the current diminishes and disappears.

3. In regions of the brain related to a special function, negative variation appears to take place during functional activity.

4. The occurrence of negative variation in an area of the brain assumed to be related to a special act at the movement of the performance of the act affords further evidence of localization.

5. These experiments afford some evidence that areas of brain related to movements of special muscles are also related to some form of sensibility in the skin adjacent to those muscles.

SECTION IN DISEASES OF CHILDREN.

J. LEWIS SMITH, M.D., NEW YORK, PRESIDENT.

Secretaries—I. N. Love, M.D., St. Louis, Mo. ; Henry Coggeshall, M.D., Mount Vernon, N. Y. ; Dillon Brown, M.D., New York ; Lucien Danransville, M.D., New York.

MONDAY, SEPTEMBER 5TH—FIRST DAY—AFTERNOON SESSION.

THE PRESIDENT, in his opening address, referred to the practical value of the papers about to be presented, and congratulated the Section on the large number of papers which had been contributed by prominent men in active practice in England, Scotland, France, Germany, and South America. The subject of intubation of the larynx would be considered in several papers. Important contributions in this connection would be read from M. Bouchut and Dr. O'Dwyer. The name of the former will always be honorably mentioned for his experiments in this direction, and Dr. O'Dwyer would be remembered by posterity as one of the benefactors of mankind.

The first paper read before the Section was by JULES SIMON, of Paris, who called attention to

A FORM OF CEREBRAL IRRITATION IN CHILDREN,

independent of organic lesion, and not the result of heredity or syphilis, but due to the deplorable tuition of young infants, even those at the breast, who are, in many cases, constantly harassed by the nurse with loud singing and sudden lights, and are liable to be excited by tea, coffee, or spirits, either directly or through the milk of the nurse. Add to these causes the feverish excitement which spreads around the cradle of the infant in modern society, and the result is a condition of cere-

bral irritation in which the child is unduly agitated by the most trivial causes. Sleep is light and frequently interrupted ; exaggerated reflexes produce vomiting, subsultus, and convulsions. The signs of precocity become more painfully evident when the child reaches the age of two or three years. He is in constant motion. The eye is restless and the expression vacant. The mind is alert, but incapable of application.

The cerebral irritation thus manifested may appear in the first months of life or it may gradually unfold itself at a later period. It terminates toward the age of five years, either by cure or by cerebral sclerosis, epilepsy, or meningitis.

It is the duty of the physician to secure a strict hygiene, with special view to prevent nervous excitement caused by unusual noises, or sights, or stimulating food and ill-advised friendly and social attentions. The open air and residence at the sea-shore or in the country are desirable, and medication, when required, should be by the bromides.

Dr. S. H. Charlton, of Seymour, Ind., had recognized the condition described by Dr. Simon, and had traced the cause in some cases to malaria and prolonged hot and dry weather. He emphasized the influence of heredity in this class of patients.

The brief communication of M. de Saint-Germain was as follows ;

" Not being able to attend the Congress, I send a note from my surgical experience. What I bring is not a stone for the edifice, not even a pebble, only a grain of sand. But each must do the best he can. Please accept the will for the deed.

" He who invents a surgical operation receives great credit. Recognition, at least, should be given him who substitutes for two operations two simple procedures, less dangerous, quite as effective, and more easy to perform. I propose ignipuncture of the tonsils and preputial dilatation in place of tonsillotomy and circumcision.

" IGNIPUNCTURE OF THE TONSILS.

" Tonsillotomy is not free from the possibility of fatal accidents. To mention uncontrollable hemorrhage and invasion of the wound by diphtheria is to make it clear that the operation is not so harmless as has been supposed.

" Krishaber tried the thermo-cautery, but his application was so superficial that treatment was indefinitely prolonged.

" I operate with the aid of a modified Smith's gag, thrusting the thermo-cautery into the tonsil to the depth of three-eighths of an inch. Two to four applications, at weekly intervals, reduces the tonsil to a shrivelled and insignificant stump.

"As to

PREPUTIAL DILATATION,

it may well take the place of circumcision, which is sometimes followed by serious hemorrhage, diphtheritic invasion of the wound, or partial gangrene.

" I reserve circumcision for those cases alone (about one in three hundred) in which dilatation is impracticable. I use a two-bladed dilator instead of the three blades of Nélaton, introducing it and slowly expanding the orifice. The operation is finished by separating the adhesions with a grooved director and is followed by daily massage, in which the glans is alternately exposed and covered.

" With both of these simple procedures I have always secured excellent and durable results, and have met with no untoward complications. In view of the great frequency of these two classes of cases, am I not right in presenting these simple and effective procedures as a surgical advance ? "

Dr. Lewis A. Sayre, of New York, then read a paper on

THE DELETERIOUS RESULTS OF NARROW PREPUCE AND PREPUTIAL ADHESIONS.

His first paper on this subject was published in the " Transactions of the American Medical Association." He was the first to draw the attention of the public to this important subject. It is now generally admitted that paralysis, and various other nervous symptoms, including a want of co-ordinating power, are in some cases induced by the pressure of the prepuce on the glans. The remedy is removal of the constriction and of the retained and concrete smegma, and such an arrangement of the parts that the prepuce shall glide *easily* to and fro over the glans, without restriction, permitting cleanliness, and thus removing one great source of danger.

For this proper arrangement of the prepuce it is necessary in some cases to perform circumcision, or an actual removal of a small portion of the prepuce, and sometimes to dissect it from *actual adhesion*, which is a very different thing from ordinary normal agglutination. But there is no occasion for removing any tissue, unless there is great redundancy *with constriction*. And in the great majority of cases the object sought can be easily accomplished by pushing a grooved director as far back as possible, and then dividing with the curved bistoury enough tissue to allow of tearing back the prepuce and uncovering the glans. The next step is to make a slight nick with the scissors, or bistoury, through the thickened fold of the edge of the frænum. Having done this, it is easy with the thumbs and forefingers to tear down the frænum and other adhesions, expose the glans, and remove from the sulcus behind the corona the hardened smegma, sometimes containing chalky concretions. In this procedure there is little loss of blood, and no loss of tissue whatever. A stitch on either side of the incision, between the skin and the mucous membrane, may or may not be required. Thus the glans is left partially covered, and it may, as well, be *freely* and *easily* uncovered. Having been responsible for bringing the subject before the profession, the writer wished to raise his voice against the mutilation and disfigurement of the organ which is often seen, which by too free removal of the prepuce leaves the glans entirely unprotected, as well as against the indiscriminate performance of the operation in cases where it can be of no avail.

The object of the paper was to harmonize two views—that of those who would operate in cases of infantile paralysis, and that of those who deny the existence of a paralyzed or even muscular inco-ordination from reflex genital irritation—by showing that there are cases of anomalous and extraordinary nervous manifestations certainly dependent on some irritation of the genital organs, in which an operation is not only justifiable, but absolutely demanded, and that in many instances the relief from all the strange symptoms has not only been immediate, but permanent after the operation, without any other medical or surgical treatment. It is also equally certain that any attempt to relieve a nervous disturbance dependent on some central lesion of the brain or spinal cord would result in no benefit whatever. The views of the writer were sustained by a large number of cases occurring in the practice of physicians in different parts of the country.

Dr. De F. Willard expressed his belief in the existence of reflex symptoms from genital irritation, and that many cases can be relieved by uncovering the glans. He advocated exposing the glans by manipulation with the thumbs and forefingers, without incision of the prepuce or frænum, continued and repeated until the prepuce is no longer tight.

Dr. I. N. Love, of St. Louis, Mo., had for many years practised circumcision. He believed in the Mosaic law from the stand-point of sanitation, morality, and the general well-being of the child. He had not succeeded in inducing mothers and nurses to secure absolute cleanliness when the sulcus is habitually covered by the prepuce.

Dr. S. C. Gordon, of Portland, Me., also advocated circumcision and believed that it should be more radically performed than it usually is.

Dr. P. R. Furbeck, of Gloversville, N.Y., recognized

the importance of uncovering the glans and securing easy motion of the prepuce, but believed in the value and importance of dilatation, because many parents refuse to accept the use of the knife. He recalled a case in which a child of six years was relieved from choreic symptoms by dilatation after circumcision had been strongly opposed.

Dr. Charles Warrington Earle, of Chicago, Ill., read a paper entitled

AN INVESTIGATION TO DETERMINE WHETHER THE ABSENCE OF SEWERAGE- AND OF WATER-POLLUTION DIMINISH THE PREVALENCE AND SEVERITY OF DIPHTHERIA.

He presented the results of a study of the causes of diphtheria in localities remote from sewer-gas influence in the less thickly populated Western States and Territories. He had received communications from a large number of physicians widely scattered over this great region.

His conclusions are briefly summarized as follows:

1. Diphtheria occurs in the mountains and prairies of the great Northwest with the same malignancy as in the East.

2. And with equal virulence in vicinities remote from sewers.

3. When once introduced, the residents of damp sod houses suffer with marked severity.

4. The infection is transported thousands of miles in some unrecognized vehicle.

5. There is abundant testimony that it follows the lines of railroads and steamers, making it imperative to increase the watchfulness and improve the methods of disinfection by railroad and steam-boat companies.

6. The desirability of legal enactments obliging people of all classes to recognize their responsibility in regard to the control of contagious diseases.

Dr. W. Foster, of Putnam, Conn., reported the apparent connection between diphtheria and exposure to filth in two cases occurring in a town of 7,000 inhabitants, otherwise entirely free from the disease. The boys affected had been playing almost constantly for several days in and about a barn, the cemented cellar of which received sink-water and house-refuse as well as manure. Isolation and thorough disinfection prevented the spread of the disease.

Dr. F. E. Waxham, of Chicago, Ill., believed that diphtheria is due rather to the absence of sewers than to their presence. An impure atmosphere and the presence of filth and decomposing vegetable matter are important factors. Absolute cleanliness, which, of course, includes disinfection, is our best resort.

SECTION ON DENTAL AND ORAL SURGERY.

Jonathan Taft, M.D., of Cincinnati, O., President.

Secretaries—A. M. Dudley, M.D., of Salem, Mass.; F. H. Rehwinkel, M.D., of Chillicothe, O.

Monday, September 5th—First Day—Afternoon Session.

The President welcomed those present.

Drs. I. V. Metnitz, of Austria; B. McLeod, of Scotland; and Greverts, of Holland, replied in behalf of the countries they represent.

The President then delivered his address, in which he reviewed the progress of dentistry in the last fifty years, and concluded by saying that although the past record was an excellent one, still the goal is not yet reached. He urged the profession, through those present, to work in all earnest for a yet higher standard.

Dr. R. J. Porre, of Cincinnati, O., read a paper on

CHRONIC PYÆMIA OF DENTAL ORIGIN.

The history of the case is as follows: The patient, male, good constitution and habits, suffered for the last thirty years from neuralgia, besides having constantly recurring furuncles and eruptions in various parts of the body, which would often for months become running abscesses. He experienced burning and itching eruptions of hands and feet, which would finally change to stubborn ulcerations. His bowels were either stubbornly constipated or exhaustingly loose. He suffered from frequent rigors and febrile attacks of varying intensity, profuse night-sweats, retention of urine, serious constriction of the bowels and urethra. Lancinating pains darted from the maxilla of right side to bowels, bladder, limbs, hands and feet, or to whatever part was locally affected at the time. This latter peculiarity, together with the discovery of a little pus exuding from the locality of the wisdom-tooth, led to a final correct diagnosis of his case.

The tooth referred to was extracted, and a speedy and complete recovery followed. As other sources leading to pyæmia and having their starting-point in the oral cavity may be mentioned pyorrhœa alveolaris, alveolar abscess, abscess of the antrum, and dental caries.

The doctor related ten other cases similar to the above, which all yielded to the simple remedy of removing the offending tooth.

Dr. J. Frank Lydston, of Chicago, Ill., said that both physicians and dentists should appreciate the important relation which morbid conditions of the mouth and jaws, and especially those which may be produced by septic absorption, bear to different general conditions. Septic matter is quite generally found about the roots of teeth, and may, under favoring circumstances, be absorbed into the blood, and there produce disturbances of greater or less degree.

The paper was further discussed by Drs. Walker, of London, England; Barrett, of Buffalo, N. Y.; W. J. Younger, of San Francisco, Cal.; and Chance, of Oregon.

SECTION IN OPHTHALMOLOGY.

Dr. J. J. Chisholm, of Baltimore, Md., President.

Secretaries—Drs. A. Alt, of St. Louis, Mo.; J. A. White, of Richmond, Va.; and R. L. Randolph, of Baltimore, Md.

Monday, September 5th—First Day—Afternoon Session.

The President, on taking the chair, expressed his high appreciation of the honor conferred upon him, and referred in feeling terms to the regret felt at the absence of Dr. E. Williams, of Cincinnati, the unanimous choice for the position. He referred to Dr. Williams as the pioneer in ophthalmology, the first of the specialties to branch out as a separate department of medical science, and the difficulties he had met with when devoting himself to diseases of the eye and ear exclusively. To-day it is acknowledged that progress in general medicine is attained only through studies and researches in special departments, and every organ has its investigator. The assembly of this International Medical Congress is, to a large extent, an assemblage of eminent specialists from great distances, at personal expense, to interchange their thoughts and conclusions upon various subjects. He referred to the vastness of the subject of the human eye alone, and that there is no disease of the eye so thoroughly mastered that further information is not desired. Operations are still far from perfect, and the origin and nature of glaucoma are not clearly defined.

The microbic element in eye-affections was also mentioned, and the intimate relation of eye-diseases to distant reflexes.

In concluding, he repeated his welcome to the members of the Section as friends and co-workers in the department of ophthalmology.

The first paper of the session was on

EYE-TROUBLES IN THEIR RELATION TO OCCIPITAL DISEASE,"

by Dr. A. Mooren, of Düsseldorf, Germany.

Dr. Mooren introduced his subject by a recital of the initial observations of Huguenin and the experimental researches of Munk, who removed the visual spheres in the occipital lobe of the dog and found that it rendered the animal blind, but left intact all the functions and movements not dependent on vision. Then, after referring to the clinical observations of Hirschberg, Pooley, Pflüger, Hughlings-Jackson, Gowers, and others, he entered into an analysis of 42 different cases of his own in which hemianopsia was present, 14 of which were on the right side, 19 on the left side, 4 temporal and 5 nasal restriction. The causes were various.

He found that hemianopsia dependent on occipital lobe-disease is not complicated with mydriasis or capillary apoplexies on the insertion of the optic nerve. It is the merit of Willbrand to have collected the different observations made in this sense. He formulates as follows:

The color-sense is to be placed on the most exterior cortex of the occipital lobe; beneath this is another layer, the centre for acuteness of vision. In a third layer beneath this again there exists, next to Gratiolet's visual radiations, the light-centre, *i.e.*, the centre for visual field. Destruction of the upper or color-perception layer may take place without affecting the underlying layers, as is demonstrated by the observations of Bjernum and Samelsohn, and Dr. Mooren's observations of the loss of color-perception in his cases without necessary impairment of vision are in accordance with those of previous observers.

He referred to the determination by Nothnagel of the occipital limits of pathological changes, by means of the method of the smaller focus. After the observations of Haab, Huguenin, Feré, and Seguin, this neurologist places the centre of optic perception in the cortex of the cuneus and first occipital convolution. This is confirmed by sections made by Curschmann.

Dr. Gradle, of Chicago, mentioned a case which appeared to him to have a bearing on the subject under discussion. A child, during an attack of what was supposed to be scarlet fever, had pain in the back of the head, which was drawn backward. Some time afterward, when seen by the narrator, it appeared to be blind, but the pupils were both quite active to light. Treatment by potassium iodide appeared to produce a beneficial result, and when last seen vision seemed to be completely restored.

The President presented in this connection a case of blindness with occipital disease. Some years ago pain began to be felt behind the left ear, shortly followed by swelling in the same region. The swelling gradually increased, and now a softish tumor of considerable size can be seen and felt, over which the bone has been absorbed. In the later period of its growth the hearing in the left ear became dull, and the right eye became blind. Patient could still read with the left eye. At that time both optic nerves appeared white and atrophic, one not more than the other. The pain has now almost disappeared, but he has only perception of light in the left eye.

The discussion was also participated in by Dr. Dickinson, of Missouri, Dr. Beerman, and others.

Dr. Ole Bull, of Christiania, Sweden, read a paper entitled

PATHOLOGICAL CHANGES IN THE RETINAL VESSELS.

He had seen eighteen cases of disease of the retinal vessels in six thousand five hundred cases of eye-disease. In some there were emboli, in others what appeared to be constriction or narrowing of the retinal vessels. He noted in some of the cases occasional spasmodic constriction of the arteries, with resulting anæmia and loss of vision, with some recoveries of vision, as distinguished from true emboli. Thrombus and gumma were referred to as causes of pathological changes in the vessels; in some cases distention, in others constriction, resulting. In all cases of organic change, serious impairment of vision or total blindness resulted.

Dr. P. D. Keyser, of Philadelphia, questioned as to whether in many of the cases it was a true embolism or a contraction of the arteries. A case which came to him blind from what appeared to be embolism, recovered good central vision, but had a field only two inches square. The treatment was galvanism. He had questioned whether, if the treatment had been commenced earlier, the vision and field might not have been entirely restored.

Dr. A. Heyl, of Philadelphia, questioned as to whether it was embolism or a loss of blood-tension, as in a case of blindness after post-partum hemorrhage, where the blood-amount is much lessened and tension much diminished. He also believed that one element in the blood-tension is the contractile force of the endothelium of the blood-vessel. When the tension is diminished this force comes into play, especially in the retinal artery as a terminal vessel without anastomosis. He cited a case of sudden loss of vision in a young lady with no heart or kidney disease, not especially anæmic, but of a somewhat waxy cast of complexion. It looked like embolism. Treatment was by palpation or percussion over the frontal and temporal adjacent region, by means of a rubber ball on a stick, and had seemed to be beneficial. He also thought that acute glaucoma might be a congestion caused by a sudden disturbance of the same nature in the circulatory system.

Dr. Bull closed the discussion by expressing his belief that many of these troubles are due to trophic affections, with no disease or affection of any organ elsewhere.

The paper by Dr. E. Smith, of Detroit, Mich., on *Treatment of Abscesses and Ulcerations of the Cornea by Jequirity*, was postponed till a later session by unanimous consent.

Dr. Leartus Connor, of Detroit, Mich., read a paper entitled

HOT WATER IN THE TREATMENT OF EYE-DISEASES.

Dr. Connor stated that that remedy was sought after which would most certainly induce, first, good feeding of the tissue; second, removal of morbid products and morbific agents; and third, the promotion of speedy repair. Such an agent is hot water in a great variety of eye-affections, such as mild catarrhal and phlyctenular conjunctivitis, corneitis, affections of the sclera and iris, and even, in some cases, retinal hyperæmia. In iritis, where the pupil refuses to respond to mydriatics, hot water will exert a marked effect in assisting dilatation of the pupil. Similar beneficial results in reducing inflammatory action had been noticed by him in catarrhal and purulent ophthalmia, in relieving the pain in glaucoma and acute dacryocystitis.

There is no morbid state of the eye on which it may not exert beneficial influence. The results reported by divers observers vary with the different modes of using it. The water should be as hot as the end of the forefinger will bear without discomfort. The method preferred by the essayist was to take a common tumbler, fill it to the brim with hot water, and, inclining the head slightly forward, apply the rim of the tumbler to the side of the nose and to the brow and cheek about the eye, which brings the eye itself actually into the water. The amount of water loses its heat slowly, and does not require frequent changing, and the eye may be kept in hot water with very little trouble for hours at a time. Antiseptics may be added, and the remedy is easily attainable with means for application. It is safe without the watchful care of the physician, while moist heat by any solid substance, as poultices, should never be used except under the direct supervision of the attendant.

Poultices are unsafe and unreliable means of applying heat to the eye; also dirty, especially on denuded surfaces. Compresses are less objectionable, and may be used as a substitute for hot water.

Local effects: 1. Contraction of blood-vessels in and about the eye. Controls hemorrhages better than cold water, and blanches the tissues in conjunctivitis, blepharitis, phlyctenulæ; and after the use of hot water the ophthalmoscope shows the retinal vessels to be reduced in size. In one case where drawings were made of the vessels before and after, the difference was very marked, and the relief of retinal congestion and improvement of vision very noticeable.

The temperature of the water must vary with the sensation of the patient. The tissues should not be exhausted.

2. Hot water will wash away or destroy all morbific secretions or excretions. At a temperature of 132° F. it destroys the bacillus of anthrax and many others, and many eyes can bear a somewhat higher temperature.

3. It promotes the healthful activity of reparative tissue or protoplasm.

4. It exerts direct power in relieving muscular fatigue and spasm.

Dr. Dudley S. Reynolds, of Louisville, Ky., asked whether the reader of the paper used hot water, as he had stated, immediately after a strabismus-operation, to increase the effect by causing contraction of the cut muscle.

In reply it was stated that contraction was stimulated in the muscle antagonistic to the cut muscle, and the effect increased in that way.

Dr. Thompson, of Indianapolis, Ind., defended the poultice as used in affections of the anterior part of the uveal tract and sclera. He had had excoriations produced by hot water, and then had to use poultices. Camomile or slippery elm, in cheese-cloth, was with him the preferable form.

Dr. P. D. Keyser, of Philadelphia, Pa., spoke of Dr. Wecker's use of hot water a long time ago in conjunctivitis diphtheritica, as he said, to soften the tissues and hasten absorption. The speaker had found diphtheritic conjunctivitis rare in this country, but membrane on the conjunctiva not so uncommon. He had used hot compresses over the eyes, and kept them hot by spraying with steam directed on the compresses from an ordinary kettle by a forked tube. The compresses should be applied over the eyes alone, and not over the frontal sinus between the eyes.

Dr. H. Power, of London, was in favor of dry poultices rather than moist ones. He has chamomile flowers or hops heated in a dry kettle, stirred till hot through, then applied in a bag or pillow to the part affected. He objects to the use of the steam from the kettle.

Dr. Eugene Smith, of Detroit, Mich., fully agreed with Dr. Power. He thinks moist heat not advisable in ulcerative keratitis.

Dr. P. T. Huckins, of Los Angeles, Cal., believes in the use of heat in these affections, but finds that the length of time during which the heat should be applied has not been spoken of.

Dr. A. Blitz, of Minneapolis, Minn., has never seen bad results in any case of conjunctival or uveal inflammations, from the use of hot water.

Dr. Abadie, of Paris, thinks that not so much stress is now laid upon the employment of hot water in many eye troubles. It has gone out of use in phlyctenular conjunctivitis, and purulent and croupous ophthalmia. In corneal affections, internal medication and proper antiseptic applications are far superior. In infectious corneal ulcers he uses iodoform powder and antiseptic washings. On the other hand, in iritis with much pain hot applications are good, but morphia, leeches, and internal administration of quinia sulphate, salicylate of soda, etc., are often all that is necessary.

Dr. Herbert, of Philadelphia, wished to call attention to a mode of applying heat that had not been mentioned, that by means of irrigation; the hot water flowing over the inflamed surface was thus kept at a constant temperature.

Dr. Calhoun, of Atlanta, Ga., spoke of an apparatus which he had sometimes used, a thin rubber bag of proper size filled with hot water and applied to the eye. It could have an inlet-pipe to supply fresh hot water, and an outlet to carry away the cooler portions.

Dr. Hotz, of Chicago, remarked that the diversity of modes of application of heat, with such uniformly good results, tends to show that there must be a principle underlying the mere material, or the manner in which it is applied. He should lay down the principle, therefore, to apply heat where there is a stagnation of blood to be broken, and it will reduce pain and promote recovery. The feeling of comfort that the patient experiences is the best gauge by which to tell the proper temperature in each particular case.

SECTION IN PUBLIC AND INTERNATIONAL HYGIENE.

Joseph Jones, M.D., New Orleans, La., President.

Secretaries—Dr. Castellanos, Dr. Felix Formento, and Dr. J. R. Le Monnier, of New Orleans, La.; Dr. B. D. Taylor, of Columbus, O.; and Dr. Walter Wyman, U.S.M.H.S., of New York.

Monday, September 5th—First Day—Afternoon Session.

The President delivered an address on the general subject of hygiene, which was the only subject considered, other than reports of committees.

He considered the question under three heads—domestic, national, and international hygiene. The first related to families and households; the second included the organization of boards of health and sanitary administration; the third, vital statistics and race distinctions.

SECTION IN MILITARY AND NAVAL SURGERY AND MEDICINE.

Monday, September 5th—First Day—Afternoon Session, Continued.

Dr. Joseph R. Smith, United States Army, read an able paper on the question of

THE BEST RATION FOR THE SOLDIER.

The author endeavored to show the difficulties in the way of ascertaining the exact amount of food that will suffice for the soldier in service, and compared the rations of different European armies, and the diets devised by various observers and experimenters. He showed that in general they err on the side of too great abundance, and briefly alluded to the proportion of carbon and nitrogen which the ration of the soldier should contain. He suggested two rations for armies, whose mean proportions of carbon and nitrogen would be about five thousand grains of the former and about three hundred grains of the latter. The paper was illustrated by numerous tables, showing the composition of the rations designed by Moleschott, Playfair, Pettenkofer, and Parkes.

In the absence of the author, Dr. John Denis Macdonald, of the British Army, his paper was read by Dr. Lloyd, of the Royal Navy. It described

A NEW FORM OF STRETCHER AND STRETCHER-SLING,

for use in the field, which displayed great ingenuity. The stretcher-sling exhibited possesses the advantage of generally distributing the weight, and of combining the support of the shoulders, loins, and hips.

The next paper in order, by Dr. Valery Havard, United States Army, was read by title.

Dr. Jeffrey A. Marston, of the British War Office, then read an instructive paper on

HUTS AND HUT HOSPITALS,

as used by the British Army in Egypt and India. He described the construction of these in detail, and offered general remarks upon the subject of camp sanitation. A hut designed by Major Marsh, Royal Engineers, illustrated with plans and sketches, was especially recommended for its portability, durability, facility of erection and removal, and low cost. These huts are constructed with projecting eaves, and a constant change of air is effected by means of ridge ventilation.

The next paper, entitled

THE CONSTRUCTION OF FIELD HOSPITALS, AS ILLUSTRATED IN THE DEPOT FIELD HOSPITAL OF THE ARMY OF THE POTOMAC AT CITY POINT, VA., IN 1864–65,

was read by Dr. James Collins, of Philadelphia.

Beginning with some general remarks on the great advantages of tents for field hospitals, he described at length the construction and general disposition of the field hospital established in 1864–65 upon the shore of the Appomattox River, one mile from City Point, Va. The hospital occupied an area of two hundred acres, and had a capacity of 10,000 men, and there was treated therein the enormous number of 71,223 men. He alluded to the excellent sanitary condition of the camp, of the means adopted for sheltering the tents from the cold winds by the transplantation of small pine-trees, the various attempts made to heat the tents by ingenious devices, with more or less success, and to the organization of the hospital. In conclusion, the speaker feelingly adverted to a visit of the late President Lincoln to the camp, on April 12, 1865.

Dr. W. Varian, of Titusville, Pa., agreed with the writer in recommending tents for hospital use, dwelling upon the fact that by their use the liabilities to the development of enteric fever and other camp diseases was greatly lessened, and that wounds of all kinds, as a rule, do well under canvas. He emphasized the importance of allowing free circulation of air between the tents, and of making the streets of a width of fifty feet, at least. The various methods of heating the camps, spoken of by Dr. Smith, he had also tried, and found that open fires made in front of the tents was the most satisfactory.

GENERAL MEETING.

Tuesday, September 6th—Second Day.

The Congress was called to order at 10 A.M. by The President.

Dr. Austin Flint, LL.D., of New York, delivered a general address on

FEVER, ITS CAUSES, MECHANISM, AND RATIONAL TREATMENT.

After discussing the subject of animal heat, the following conclusions were reached by the author:

1. Fevers, especially those belonging to the class of acute diseases, are self-limited in their duration, and are due each one to a special cause, a micro-organism, the operation of which ceases after the lapse of a certain time.

2. We are as yet unable to destroy directly the morbific organisms which give rise to continued fevers; and we must be content, for the present, to moderate their action and to sustain the powers of resistance of patients.

3. The production of animal heat involves oxidation of parts of the organism or of articles of food, represented in the formation and discharge of nitrogenized excrementitious matters, carbonic acid and water.

4. As regards its relations to general nutrition and the production of animal heat, water formed in the body by a process of oxidation is to be counted as an excrementitious principle.

5. Fever, as observed in the so-called essential fevers, may be defined as a condition of excessive production of heat, involving defective nutrition or inanition, an excessive production and discharge of nitrogenized excrementitious matters and carbonic acid, with waste and degeneration of the tissues, and partial or complete suppression of the production and discharge of water.

6. Aside from the influence of complications and accidents, the ataxic symptoms in fevers, the intensity and persistence of which endanger life, are secondary to the fever, and are usually proportionate to the elevation of temperature. These symptoms are ameliorated by measures of treatment directed to a reduction of the general temperature of the body.

7. The abstraction of heat by external cold and the reduction of temperature by antipyretics administered internally, without affecting the special cause of the fever, improve the symptoms which are secondary to the pyrexia.

8. In health, during a period of inanition, the consumption of the tissues in the production of animal heat is in a measure saved by an increased production and excretion of water.

9. In fever, the effects of inanition, manifested by destruction and degeneration of tissues, are intensified by a deficient formation and excretion of water.

10. Alimentation in fever, the object of which is to retard and repair the destruction and degeneration of tissues and organs, is difficult mainly on account of derangements of the digestive organs; and this difficulty is to be met by the administration of articles of food easily digested, or of articles in which the processes of digestion have been begun or are partly accomplished.

11. In the introduction of hydrocarbons, which are important factors in the production of animal heat, alcohol presents a form of hydrocarbon which is promptly oxidized, and in which absorption can take place without preparation by digestion.

12. Precisely in so far as it is oxidized in the body, alcohol furnishes matter which is consumed in the excessive production of heat in fever, and saves destruction and degeneration of tissue.

13. The introduction of matters consumed in the production of heat in fever diminishes, rather than increases, the intensity of the pyrexia.

14. As the oxidation of alcohol necessarily involves the formation of water and limits the destruction of tissue, its action in fever tends to restore the normal processes of heat-production, in which the formation of water plays an important part.

15. The great objects in the treatment of fever itself are to limit and reduce the pyrexia by direct and indirect means; to limit and repair destruction and degeneration of tissues and organs by alimentation; to provide matters for consumption in the abnormal production of heat, and thus to place the system in the most favorable condition for recuperation after the disease shall have run its course.

SECTION IN ANATOMY.

Tuesday, September 6th—Second Day—Morning Session.

The first paper read was on

THE ANATOMY AND SURGICAL IMPORTANCE OF THE PERI-RENAL CELLULO-ADIPOSE TISSUE AND RENAL CAPSULE,

by L. H. Dunning, M.D., South Bend, Ind. After outlining the position of the kidney and its anatomical relations, he then called attention to a double form of the peri-renal cellulo-adipose tissue, which, he thought, was a wise provision of nature and of great surgical importance. He explained the anatomy of the renal capsule, the arrangement of the fat, and the position of the cellular tissue, thus preventing the stretching of the nerves and the accompanying pain. In speaking of the cap-

sule, he thought it acted as a barrier to prevent inflammation to and from the kidney, and also furnished a surface for the attachment of the peri-renal cellulo adipose tissue. The surgical importance of this peri-renal cellulo-adipose tissue and of the renal capsule lay in the fact that one or both were often subject to inflammation and morbid changes, and that they were often invaded by the surgeon. Tumors often occurred within or upon the fibrous cellulo-adipose tissue of the kidney. The question was now if there were real danger attendant upon these invasions into the renal territory. In the three most frequent operations upon the kidney—nephrorrhaphy, nephro-lithotomy, and nephrectomy—the peri-renal cellulo-adipose tissue was cut through. The adipose and fibrous tissue, which was very vascular in this region, was very liable to inflammations. In operating, all loose portions of fat should be removed and the fibrous capsule, or even a small portion of the cortical portion of the kidney, might be left. The author asked also what should be done with the cellulo-adipose structure and the fibrous capsule left behind. His supposition, from the careful observation of several cases and a second operation on one, that after removal of the kidney the cavity was partially collapsed and filled with granulations, and this scar-tissue took the place of the kidney. These fibrous bands continued to contract, displacing the surrounding tissue. His final opinion was to remove all tissue when it was not too vascular.

The President spoke of the important point mentioned by Dr. Dunning, in regard to the close connection between the movements of the diaphragm and of the abdominal organs. He was of the opinion that the whole kidney could be destroyed and the capsule be left.

Dr. W. T. Oppenheimer, of Richmond, Va., then exhibited several photographs of

AN APPARATUS FOR THE TREATMENT OF FRACTURES OF THE SURGICAL AND ANATOMICAL NECK OF THE HUMERUS.

He spoke of the great difficulty in keeping the fractured extremities of the bone in apposition, and thought that his apparatus covered the three necessities of extension, counter-extension, and fixation. The apparatus consisted of strong iron bands, which were fastened around the thorax by means of plaster of Paris, and which extended to the fractured arm, holding it firmly at the shoulder, upper arm, and forearm. He had used it in several severe cases of fracture of the neck of the humerus, and suggested using it in fracture of the clavicle and in excision of the elbow-joint.

The President asked when passive motion was commenced.

Dr. Thomas, of Pittsburg, Pa., thought it did not matter what apparatus was used, so long as the arm was held out from the body. He admitted, however, that he had never treated a case in that way, but thought it formed the principle of Dr. Oppenheimer's apparatus.

Dr. Oppenheimer replied that in about five weeks passive motion was commenced. He said when the plaster jacket was put on well, and the bands were strong, that no movement of the body could cause crepitation.

The President asked if a corset of leather or of other material could not be used instead of the plaster of Paris, which, in his opinion, seemed a little clumsy for such treatment. He also thought that in using crepitus there was danger of tearing the periosteum, and thus cutting off the blood-supply of the fractured ends.

Afternoon Session.

PRESIDENT'S ADDRESS.

Dr. Pancoast, after greeting the members of the Section, began by saying that anatomy was sometimes called a dead study, but he thought it was a live subject. He thought that many advances had been made since the last meeting of the Congress, and especially in the anatomy of the brain. Great progress had also been made in microscopical anatomy. The study of the electrical sensibility of the brain and the operations for the cure of epilepsy by Hughlings-Jackson, Ferrier, and others had proved itself to be very successful. The ability to localize brain-troubles by the part paralyzed was evidence of great practical advances in the study of brain-surgery. He then related a very interesting case of his own of a gun-shot wound of the brain which he had successfully treated by aid of a careful study of the symptoms and the use of the induction balance. He did not think that anatomy made it sufficiently distinct that all muscles from one bone to the bone below were articular muscles. This was shown in a paralysis of the deltoid muscle making a simulated dislocation. He defined a joint at that division of the skeleton made to deaden shock and cause motion. He spoke of the low vitality of the joint-cartilage and the snowy-white membrane observed on the articular cartilage in white swelling. He did not altogether approve of extension and counter-extension in diseased joint, and thought that rest was important and that it was sufficient to prevent the rubbing together of the diseased surfaces. He believed that there were only four metacarpal bones in each hand and referred to the development of the hand and foot as a proof. He mentioned several anomalies of muscles which had come under his observation, such as two heads to the latissimus dorsi, and particularly of an unequal development of the soleus and gastrocnemius, wherein the latter muscle was too long. In certain forms of talipes with this muscular condition, a cutting of the tendo Achillis failed to effect a cure. The tense soleus had to be alone divided by slipping the knife between the two muscles and cutting the soleus. He thought that the deep fasciæ were not only for protection but acted as ligaments. He mentioned fractures of the coronoid process of the ulna and their causes, and was of the opinion that muscular contraction of the brachialis anticus could not break the coronoid process because the latter was covered by the anterior ligament of the joint. He thought the word anastomosis as applied to nerves and tissue incorrect, and should only be used when speaking of vessels. He explained the direction of the nutrient arteries in the long bones of the extremities and the peculiar position of the fœtus in utero causing their direction, and the importance of understanding the entrance of these nutrient vessels into the bones in some fractures. He thought many names might be simplified and spoke of the recent study of the skull and spinal column. He concluded by quoting the authorities on the advances made in the study of anatomy in different parts of the world.

Dr. Albert B. Strong, of Chicago, Ill., then read a paper entitled

FROZEN SECTIONS OF THE MALE PELVIS, SHOWING RELATIONS OF PERITONEUM TO RECTUM, BLADDER, AND THE MEDIAN LINE OF ABDOMINAL WALL, WITH SPECIAL REFERENCE TO SUPRAPUBIC CYSTOTOMY.

He exhibited some very well-executed reproductions of photographs of elaborately prepared specimens. He found air better than water to lift the bladder and its peritoneal reflection out of the pelvis. He found that distending the rectum first and the bladder afterward, and moderately distending both, met the indications the best.

Dr. Gervais, of Belgium, always punctured the bladder when the patient was standing and the bladder filled.

Dr. F. C. Schaefer, of Chicago, Ill., then read a paper entitled

ANATOMICAL POINTS INVOLVED IN THE LOSS OF COMPLETE SCALP, INCLUDING ONE EAR AND THE GREATER PORTION OF THE EYELIDS.

This paper was founded upon a case in which a girl in a factory was caught by the hair and scalped. He had

not been able to find many such cases on record, but was of the opinion that the results heretofore obtained had not been very successful. He at first attempted, against his own judgment, to replace the scalp, but was unsuccessful; he then began skin-grafting, with which he had obtained very satisfactory results, which his excellent photographs of the case proved. He was of the opinion that small grafts, placed close together, were better than large ones; that grafts with the subcutaneous tissue were the best kind; that auto-dermal grafts were better than dermal grafts; that grafts from a person near the same age as the patient were more successful. He thought that the grafts so placed were probably nourished by osmosis. He found that grafts in a new wound grew much faster than those in an old one.

Dr. Murphy, of Chicago, Ill., emphasized the importance of taking dermal grafts with plenty of subcutaneous tissue.

The President thought that grafts taken from the scalp itself might have grown successfully.

Dr. F. C. Schaefer, in closing, said that in his case the machinery had so mangled the scalp that it was entirely bloodless when examined. He also drew the distinction between skin-grafting and a plastic operation, which was, of course, an entirely different thing.

SECTION ON DENTAL AND ORAL SURGERY.

Tuesday, September 6th—Second Day—Morning Session.

Dr. William Carr, New York, N. Y., gave a *clinic* on the

TREATMENT OF FRACTURES OF THE MAXILLÆ WITH MODIFIED INTERDENTAL SPLINT.

The majority of fractures of the inferior maxilla occur in the body rarely at the symphysis menti, but usually directly anterior or posterior to the mental foramen. A noticeable fact in connection with these fractures is that the victim rarely applies for treatment for several days succeeding the injury. He realizes that some of his teeth are loosened and also that he is painfully bruised, but does not seek surgical aid until he becomes alarmed by the increased inflammatory condition of the parts. There is but little difficulty in establishing a correct diagnosis, as usually the following symptoms are present—great pain in the effort to open and close the mouth, swelling, crepitus, inflammation, inability to masticate, and marked irregularity of the teeth.

Treatment.—It is identical with that of other fractures, namely, to bring the parts into apposition and retain them firmly until ossification is completed. For treatment of fractures of the maxillæ there is nothing superior to the interdental splint. When properly adjusted, speedy union may be secured without deformity of the jaw or irregularity of the teeth. Before taking the impression a careful examination of the parts should be made. Loose teeth and spiculæ of bone should be removed, and the parts should then be brought as nearly as possible to their normal position. An accurate impression should be made with impression-compound or wax. The material used should be as warm as the patient can bear it, in order to prevent unnecessary pain and also to prevent further displacement of the parts. The splint is made of vulcanite and covers all the teeth of the lower jaw, and all the teeth posterior to the canine in the upper jaw—leaving a space of about three or four lines through which the patient may receive nourishment. Small holes are drilled in the splint over the grinding surface of each molar for the purpose of ascertaining whether its adjustment is proper.

The splint should first be adjusted to the sound jaw, then gently bring the fractured jaw into position until it has passed about two-thirds of the length of the teeth—then with a quick, firm motion bring the parts into position. Next apply a four-tail bandage, which should be retained from three to five days; after this time, in the majority of cases, it may with safety be removed during the day but should be replaced at night until the removal of the splint. The patient should be furnished with an ordinary rubber syringe, and instructed to keep the mouth thoroughly cleansed. For disinfectants I use peroxide of hydrogen, three per cent. solution, or a solution of bisulphate of soda in the proportion of ʒj. to ʒj. of water.

In ordinary cases the splint should be retained for three or four weeks, according to the physical condition of the patient—unless unforeseen complications should arise. The application of the splint, combined with thorough cleanliness, will usually be all the treatment required.

The advantages, besides those previously stated, are that the patient experiences but little pain and inconvenience, and can, as a rule, attend to his business almost immediately after the splint is applied.

It is not necessary that all the teeth, nor, indeed, that any should be present in the mouth in order to make this splint serve its purpose. In the first case the rubber can be made to take the place of the missing teeth, and in the latter case a perfect adaptation of the splint to the alveolar ridges can be secured, and will be found to keep the parts in perfect apposition.

Should it be deemed advisable to place a splint in position within an hour or two after seeing the case, one can be constructed entirely of ordinary gutta-percha, with just enough wire inside to stiffen it. Dr. Carr demonstrated this last method; it is very simple and can be made by any surgeon.

A number of gentlemen examined the principle and pronounced it very satisfactory in every way, the main points being its simplicity of construction, its effectiveness, and the ease with which it is adjusted and worn by the patient.

Dr. E. Brasseur, of Paris, France, read a paper on

THE USE OF AIR IN DENTAL THERAPEUTICS.

The reader urged that the ordinary means, such as bichloride and biniodide of mercury and carbolic-acid crystals, for destroying microbes in the oral cavity and, especially, in carious cavities of teeth, should be supplemented by the use of hot air.

Dr. C. A. Brackett, of Newport, R. I., discussed the paper at some length, laying considerable stress on the efficacy of crystallized carbolic acid as a germicide in carious cavities in teeth.

Other remarks followed by Drs. James Truman and W. H. Morgan.

Afternoon Session.

Dr. Junius E. Gravens, of Indianapolis, Ind., read a paper on

THE MANAGEMENT OF PULPLESS TEETH.

This system is based on the proposition that a pulpless tooth is not necessarily dead. The pulp being devitalized, the tooth still retains life through its pericementum. The usual course of treating pulpless teeth with escharotics and irritants causes irritation and final destruction of the pericementum, and the result is that the tooth, instead of being preserved, will act as a foreign body, and will be thrown off by nature through abscesses; or, worse still, will lead to no end of nervous derangements.

The treatment suggested by the reader is to thoroughly cleanse the pulp-canal, and at once hermetically seal it with tin-foil.

The paper was discussed by Dr. Thomas Fillebrown, of Portand, Me. He did not agree with the essayist in the method outlined in the paper. The doctor gave a short synopsis of the method he employs in treating pulpless teeth, which, by the manner in which it was

received by the Section, seemed to be the one generally pursued.

Dr. A. W. Harlan, of Chicago, Ill., followed, and likewise objected to the views expressed by the essayist. A dead pulp produces no irritation in the canal; the disease which it causes is beyond. If you could mechanically displace an odor—which the speaker denied—and should then fill the root-canal without any disinfection, disaster would inevitably follow unless there should be a fistulous outlet.

Dr. W. C. Barrett, of Buffalo, N. Y., in discussing the paper, stated, whether viewed from the stand-point of pathology or etymology the paper was alike remarkable. That such a mass of absurdities could be presented at a meeting of the world's representatives in dentistry was to him astounding, and he protested against its acceptance as the standard by which to judge the intelligence of American dentists. Why the exploded dogmas of twenty-five years since should be gravely and in all sincerity presented at such a meeting as that, was, he must confess, something for which he was not prepared. The assertion that a closed chamber in which exist the septic débris and the products of decomposition of a tooth-pulp should not be opened and evacuated, he could scarcely believe was made in calm earnest. The essayist had exhibited his complete ignorance of the progress of the past century.

Modern antiseptic pathology has taught us certain facts, and among these is the knowledge that the first step in the treatment of aseptic cavities is complete drainage; second, disinfection and the removal of all the products of disorganization; third, destruction of septic organisms; and finally, the complete sealing of the cavity against further infection. These comprise the essential steps in the treatment of septic root-canals. He would not insult the intelligence of those present by presuming to enlarge upon this and by going into the details of treatment, for that was not a body of tyros. But he did object to a consideration of the subject from the low stand-point of this extraordinary paper.

Dr. T. E. Weeks, of Minneapolis, Minn., read a paper on

MATRICES AS ADJUNCTS IN FILLING TEETH.

The essayist reviewed the different appliances for simplifying what would otherwise be very laborious operations. A perfect matrix should be simple in construction, cheap, easily adapted, and not too stiff, so that when applied it will yield just enough to allow sufficient gold to pass beyond the walls of the cavity for a good finish.

Dr. F. H. Guilford, of Philadelphia, Pa., in a few brief remarks, indorsed the sentiment expressed in the paper.

SECTION ON CLIMATOLOGY AND DEMOGRAPHY.

Tuesday, September 6th—Second Day.

The Section met at 11 A.M. The following resolutions, submitted by The President of the Section, were discussed and, after verbal amendments, unanimously adopted:

Resolved, That in the opinion of the Section on Medical Climatology and Demography of the Ninth International Medical Congress, assembled in the city of Washington, September 5–10, 1887, it is important there should be established in every country a national department, bureau, or commission for the record of vital statistics upon a uniform basis, to include not only accurate returns of births and deaths, but the results of collective investigation by government officials of facts bearing upon the natural history of disease as manifested among men, women, and children separately, especially with regard to climatic and other discoverable causes of the several forms of disease—race, occupation, and residence being included—that necessary preventive measures may be determined and enforced for the preservation of the public health.

Resolved, That the Secretary-General be requested to have the expression of opinion communicated to the several governments.

Dr. Charles Denison, of Denver, Col., read a paper on

THE PREFERABLE CLIMATE FOR PHTHISIS.

The paper was elaborately illustrated by maps, diagrams, and tables. Dr. Denison believes that the climate to be preferred for the great majority of consumptives in the United States varies from between fifteen hundred feet elevation in the North in winter to ten thousand feet in the Southern portion in summer. Certain contraindications exist against sending consumptive patients to high altitudes. The most prominent of these are advanced age of the individual; an excitable, nervous temperament; valvular lesions, with rapid action of the heart; marked and extensive emphysema; pneumothorax and hydro-pneumothorax; active pneumonia or hæmoptysis; high bodily temperature; extensive involvement of lung-tissue, and similar conditions.

He takes the affirmative side of the following five divisions named in the order of their relative importance: (1) Dryness as opposed to moisture; (2) coolness or cold preferable to warmth or heat; (3) rarefaction as opposed to sea-level pressure; (4) sunshine as opposed to cloudiness; (5) variability of temperature as opposed to equability.

Dr. John William Moore, of Dublin, Ireland, then read a paper on

THE SEASONAL PREVALENCE OF PNEUMONIA.

The conclusions—pneumonia has claims to consideration as a specific fever on the following grounds:

1. Its not infrequent epidemic prevalence, which is beyond dispute.
2. Its proved infectiveness.
3. Its occasional pathogenic origin in many cases.
4. Its mode of onset or "invasion," which exactly resembles that of the recognized specific fevers.
5. The appearance of constitutional symptoms before the development of local signs or symptoms.
6. The critical termination of the febrile movement in uncomplicated cases.
7. The presence of local epiphenomena in connection with the skin, as herpes, taches bleuâtres, and desquamation.
8. The development of sequelæ in some cases, such as nephritis, followed by renal dropsy and other conditions.
9. The discovery of a probable pathogenic bacillus, to which analogy points as pathognomonic.

Dr. Moore concludes his paper in these words: "The day is seemingly not far distant when we shall speak of pneumonic fever in precisely the same way as we use the term enteric fever at present; that is, to signify a zymotic or specific blood-disease, manifesting itself after the lapse of a certain time—the period of incubation—by physical phenomena, objective and subjective, connected in this instance with the lungs."

THE RELATIONS OF CERTAIN METEOROLOGICAL CONDITIONS TO ACUTE DISEASES OF THE LUNGS AND AIR-PASSAGES.

Dr. Henry B. Baker, of Lansing, Mich., read a paper on the above subject, which was illustrated with diagrams that showed curves for influenza, tonsillitis, croup, bronchitis, and pneumonia, which follow the curve for atmospheric temperature with surprising closeness.

He suggests that the explanation of the causation of these diseases has not been grasped before because one of the principal facts has not been apprehended, namely, the fact that cold air is always dry air; on the contrary,

it has been generally stated that when these diseases occur the air is cold and damp. He explains that while the cold air is damp relatively, it is always absolutely dry, and he thinks that its bad effects on the air-passages are mainly through its drying effects, which can best be appreciated by reflecting that each cubic foot of air inhaled at the temperature of zero Fahr. can contain only one-half grain of vapor, while when exhaled it is nearly saturated at a temperature of about 98° F., and therefore contains about eighteen and one-half grains of vapor, about eighteen grains of which have been abstracted from the air-passages. Thus cold air, falling upon susceptible surfaces, tends to produce an abnormal dryness, which may be followed by irritation and suppuration. He claims that coryza is sometimes so caused. Under some conditions the nasal surfaces are not susceptible to drying, the fluids being supplied in increased quantity to meet the increased demand made by the inhalation of cold air. In that case an unusual evaporation of the fluid leaves behind an unusual quantity of non-volatile salts of the blood, such as sodium chloride, and an unusual irritation results; he thinks influenza is the name commonly given to this condition.

The effects which the inhalation of cold air have on the bronchial surfaces depend greatly upon how the upper air-passages have responded to the increased demand for fluids; because, if they do not supply the moisture, it must be supplied by the bronchial surfaces, in which case bronchitis results. Finally, if the demands for moisture made by cold air are not met until the air-cells are reached, pneumonia is produced.

He refers to statistics which he has published, showing that even the rise and fall of such contagious diseases as scarlet fever, diphtheria, and small-pox follow the same laws shown to control in the acute diseases of the air-passages, and he offers the explanation that the irritations and exudations in the air-passages caused by the inhalation of cold dry air supply a nidus for the contagia, and are thus the predisposing causes of those diseases. As to whether or not pneumonia is a contagious disease he offers no evidence except that nearly all of the phenomena seem to be accounted for without the necessity of supposing a special contagium. For the abnormal accumulation of the non-volatile salts of the blood through evaporation of the fluids in the air-cells, so as to cause inflammation and exudation, time is required; therefore, he does not believe that a sudden and short exposure to cold can ordinarily produce pneumonia, except the short exposure follow or precede somewhat prolonged inhalation of cold dry air; although he thinks that lobar pneumonia may have just that causation, the reason for the chill and for the limitation of the area of the exudation being the disturbance of the nervous equilibrium associated with the more or less complete paralysis of the small blood-vessels in that part of the lungs supplied by one particular nerve, some or all the endings of reflexions of which have been suddenly exposed to the enervating influence of warmth following the exposure to cold.

SECTION IN THERAPEUTICS.

Tuesday, September 6th—Second Day.

Dr. Hugh Hamilton, of Harrisburg, Pa., read a paper on

THE CHEMICAL PHILOSOPHY OF REMEDY.

Activity in bacteriology and advances in chemistry suggested that there is a chemical philosophy in remedy. Doubtless germs are active in altering, by fermentation, the normal organic constituents of the blood into noxious ones not infrequently fatal (Jaksch, 1887): "To assist in clearing the system of this life-activity or aid in rapidly removing these effete bodies constitutes the aim of remedy; so that *remedy* might be defined as the use of means to restore the body to healthy condition by prophylaxis—repair of injury and the correction of nutrition."

The success of antiseptic surgery shows the effects of the application of this principle to diseased conditions. Germs contain albumen; so if subjected to the physical effects of vacuum, freezing, boiling, or incineration, suffer or perish. Chemically, they succumb to the use of mineral acids, alkalies, certain salts, and organic radicals: In a word, the deprivation of oxygen, either directly by oxidation of another substance capable of attracting and retaining it, by the loss of hydrogen, by the subtraction or substitution of elemental or approximate radicals. Consequently we can *exclude*, *arrest development*, or totally *destroy* the bacteria. The ptomaïnes engendered by bacteria are divided into several classes, and upon subsequent elemental analysis show that they contain certain homologues of organic radicals (Cornil and Babes). The application of disinfectants suggested antiseptics, and leads us to anticipate their modified use in internal medicine.

Clinical experience shows that remedies, although often empirically selected, are those containing efficient oxidizers, active appropriators of hydrogen, or by substitution of radicals succeed in destroying the pernicious products of germs, their spores, or the consequences of their mere existence in the vital fluid.

The paper was illustrated by diagrams and charts.

Dr. William Murrell, of London, England, said that the subject was one of very great interest. The philosophy of remedy was very generally passed over by the workers in therapeutics. The only men who appeared to have done much in this field were Professor Wormley, of Philadelphia, and Dr. Stockman, of Edinburgh, who had been doing very valuable work in this branch.

Dr. Ralph Stockman said that the work referred to had been carried on in connection with a friend, he having assisted in matters of technique and experimentation. He had been struck with the paucity of information contained in text-books, especially with regard to the causation of fever and emaciation. Most writers attribute these to the breaking up of the tissues under the effect of the disease. Dr. Philip, of Edinburgh, has recently made a very interesting investigation into this condition. He found that by taking the sputum of a phthisical subject, protecting it with great care from contamination by external agents, and maintaining it for a short time at the temperature of the body, that an alkaloid was obtainable by Stas' process, which was evidently an alkaloid, a ptomaïne. This substance was also detected in the cavities of phthisical lungs. When this substance was injected into mammals it produced fever and progressive emaciation, which proceeded to a fatal termination, even where the injections were discontinued. In frogs the same results were obtained, except that recovery sometimes followed. It was also found that if belladonna and atropine were administered after the new alkaloid had been injected, that the pulse regained its strength, emaciation and fever were checked, and the animal recovered. This is a corroboration of the clinical value of atropine in the treatment of phthisis, to which Bartholow called attention some years ago.

Dr. Coghill was impressed with the value of this work. In confirmation of the remarks of the last speaker, he said that the dose of atropine which could be well borne in phthisis was very much larger than in health. This seemed to warrant the opinion that there was some counteracting agent present in the economy in phthisis which was not present in health.

Dr. J. S. Sinclair Coghill, of Ventnor, Isle of Wight, England, read a paper on

CHLORATE OF POTASH.

After a historical résumé of the introduction of this agent into modern therapeutics, he discussed the various theories which have been advanced as to its action, and rejected the idea that it was decomposed and yielded its

oxygen to the blood. A number of experiments was detailed upon the human subject, from whom nearly all the salt given was afterward obtained from the urine. "As a salt exceptionally rich in oxygen, it has, without decomposition, the valuable property *per se* by its mere presence, apparently by oxygenating or aërating the blood, and so, by restoring or exalting this vital character of the circulating fluid, influencing to a corresponding degree the nutrition and functional activity by the various tissues and organs of the body. Beyond this it does not appear to have any specific action in any disease." The beneficial effect of this agent upon inflammations of the throat and other mucous membranes has been established by experience. The ordinary lozenges are too strong and are liable to exert a caustic action upon the mouth; he uses only two and a half grains in each troche, with white sugar. This, in combination with arsenic internally, is almost a specific in clergyman's sore-throat. It is a valuable tonic and stimulant in cases of cardiac debility and impoverished blood, as in anæmia and chlorosis. It is remarkable what effect this has upon the development of the fœtus, when given during the whole course of pregnancy. Several very interesting cases were cited.

Dr. H. A. Hare, of Philadelphia, said that potassium chlorate does not yield oxygen to the blood, and cited a case of poisoning in which bacteria was found in the kidneys.

Dr. J. Solis-Cohen, of Philadelphia, said that he was much pleased with the paper, and was in the habit of using chlorate of potash in diphtheria. He believed that all the chlorides were useful in this disease.

Dr. Traill Green, the President, advocated the use of sodium chlorate as a less depressing agent, all potassium salts being depressing. He asked if this salt is used in England.

Dr. Murrell said that since the publication in the *Lancet* of Dr. Sainsbury's paper, some years ago, the sodium salt was used very largely in preference to the potassium chlorate.

Dr. G. L. Magruder recommended potassium chlorate in catarrhal affections of the bowels in infants in combination with chalk mixture.

Dr. Frank Woodbury, of Philadelphia, Pa., said that a therapeutic agent need not be decomposed in the body in order to influence nutrition (*i.e.*, sodium chloride). He believed that the potassium chlorate has a limited range of therapeutic usefulness, within which it cannot be substituted by any other salt. In some cases it is very depressing, and its indiscriminate use should be condemned, as collapse may be caused in an ordinary catarrhal pharyngitis, and thus lead to the idea that the case is really diphtheria. It is important to watch the renal secretion, since the salt is not very soluble, and where there is a deficiency of water, crystals of the salt may be deposited in the tubules and give rise to irritation and congestion of the kidneys.

Dr. F. E. Steward, of Wilmington, Del., had found it useful in correcting foul breath.

Dr. Charles D. F. Phillips, of London, read a paper entitled

THE ACTION OF CERTAIN DRUGS ON THE CIRCULATION AND SECRETION OF THE KIDNEY.

This contained a number of very interesting experiments, made with Roy's onkometer, with caffein, spartein, strophanthin, digitalin and ulexin.[1] He concluded that the flow of urine is not so much dependent on the blood-pressure as on the rate of flow of the blood in the renal vessels. With regard to this point, it is necessary to remember that, although such drugs as strophanthin produce a great increase in the *force* of the cardiac beats, yet these are very much slowed, so that it is quite possible that although the heart's action is stronger, yet the total amount of blood sent through any given organ, such as the kidney, in a given time, may remain the same. Whereas such a drug as digitalis, producing as it does a rise of blood-pressure and a contraction of the kidney-vessels, may cause an increased quantity of blood to pass through the renal vessels. On this view one could find the explanation of digitalin being a diuretic, and strophanthin not being one.

Inasmuch, however, as spartein has not so marked diuretic action, we must also assume that digitalin must have some peripheral action on the secretory apparatus of the kidney.

His results were tabulated briefly as follows, in three divisions:

(A) DRUGS THAT FIRST CONTRACT, AND AFTERWARD DILATE THE KIDNEY.

(1) *Caffein*—in small doses—induces in the stage of contraction a fall of blood-pressure—in that of expansion, a slight rise. During the former, the flow of urine *may* be arrested; during the latter it is always increased, such increase depending on dilatation of renal vessels.

(The possible *arrest* of secretion during the first stage is special to caffein, and may be induced by large or repeated doses.)

(2) *Ulexin*—gr. $\frac{1}{6}$—greatly raises blood-pressure during the first stage (that of contraction); in the second, expansion is much greater in degree but shorter in duration than under caffein, and is accompanied by brief but marked increase in urinary flow; the effective dose is limited by its toxic action on respiratory centres. Practically, *excess* of caffein induces only the first stage—*excess* of ulexin only the second.

(B) SUBSTANCES THAT DILATE THE KIDNEY, BUT TO LESS EXTENT AND MORE SLOWLY THAN CAFFEIN AND ULEXIN,

are dextrose, urea, sodium chloride, and acetate, and probably all constituents of the urine.

(C) DRUGS THAT CONTRACT THE KIDNEY WITHOUT SUBSEQUENT EXPANSION.

(1) Digitalin, with *increased* secretion of urine (probably resulting from general heightened blood-pressure).

(2) Spartein, with *diminished* secretion (in health at least).

(3) Strophanthin causes slight temporary contraction, with no marked increase of secretion.

(4) Apocynëin, similar temporary contraction, and no definite increase of secretion.

(5) Turpentine; (6) adonidin; and (7) barium chloride give similar results.

In conclusion, it seemed to him that the plethysmographic method of experimentation is a valuable one for determining the exact action of drugs on the circulation, and one that deserves more attention than it has hitherto attracted.

Dr. Murrell referred to the importance of this study of diuretics, since so little is known, comparatively, of their effects. Diaphoretics are well understood, but the action of diuretics remains to be worked out. He could not understand the points of superiority of the instrument used over Marey's tympanum.

Dr. Phillips said that Roy's onkometer was simpler, easier to work, and more accurate in its results.

Dr. Woodbury inquired if any estimation had been made of the solid ingredients of the urine excreted during the experiments. He regarded water as merely incidental. The urine of snakes is solid. It is of primary importance, in determining the value of a diuretic agent, that its effect upon the excretion of the urinary salts (urea, urates, creatin, creatinin, and allied bodies) shall be ascertained.

Dr. Phillips said that these experiments were yet in their infancy and incomplete, but at a future time the

[1] Ulexin is an alkaloid from the gorse, *Ulex europæus*.

chemical composition of the urine will be communicated.

Dr. Samuel S. Wallian, of New York, read a paper on

THE NEGLECT OF NON-MEDICINAL THERAPEUTICS,

in which he urged the abandonment of drugs, and a resort to baths, massage, electricity, and hygiene.

SECTION IN DISEASES OF CHILDREN.

TUESDAY, SEPTEMBER 6TH—SECOND DAY—MORNING SESSION.

Dr. Moncorvo read a paper on

HEREDITARY SYPHILIS AND RICKETS IN BRAZIL.

In an extensive practice in Rio de Janeiro and the province of that name, he believed that hereditary syphilis furnishes sixty per cent. of the cases of infantile disease. It is the most important factor of infant mortality, either directly or by the severity which it imparts to the diseases of children, and rickets makes its appearance in forty-five per cent. of the children that come under his observation. This does not accord with the opinion of Dr. Charles West, who stated in the Congress of 1881 that while syphilis was common in Brazil, rickets was unknown.

More than two-thirds of the rickety children in his practice show signs of syphilis, and it is rare to find an hereditary syphilitic child whose bones are not deformed by rickets.

Although not prepared to demonstrate the etiology of rickets on these grounds, he believed that hereditary syphilis is an important factor.

A paper was read by Dr. William Stephenson, of Aberdeen, Scotland, on

THE RATE OF GROWTH IN CHILDREN.

But little had heretofore been known in regard to the rate of growth in children, and nothing whatever of its clinical bearings. Many important questions arise in this connection. For instance, if a boy in a given year adds to his weight double or treble the number of pounds which he does in another year, is he on account of this increase of cell-activity the more or the less able to bear a strain, such as school pressure or physical labor?

By combining the tables of Dr. Bowditch and those of the Anthropological Committee of the British Medical Association, Dr. Stephenson had tried to construct a standard of the rate of growth from the fifth to the eighteenth year, for all the English-speaking races.

In the charts exhibited, the graphic line representing the annual increase in weight presents a curve of similar type in girls as in boys, but differing in the times of maxima and minima. The most striking difference is seen in the fact that the maximum rate of growth occurs in girls from the eleventh to the thirteenth year, and in boys from the fourteenth to the sixteenth year.

From his study of the tables and charts the author is of the opinion that the critical and trying character of the period known as puberty is due to the fact that the great activity of growth which occurs then makes a serious demand on the system, rather than to the fact that the reproductive organs are about to reach complete development. Reference was made to important results to be obtained from comparisons in rate of growth between children of the poor and rich, and of the professional, commercial, and artisan classes.

A paper was then read by Professor Victor C. Vaughan, of the University of Michigan, on

THE USE OF COW'S MILK IN THE ARTIFICIAL FEEDING OF INFANTS.

Three years ago a writer had isolated the active principle from poisonous cheese. He had named it tyrotoxicon. Later he found the same principle in milk, ice-cream, and other articles of food. In experimenting with this poison it was found that its action on the lower animals produced the phenomena of cholera infantum. The symptoms and the post-mortem appearances were identical. From this it is easy to understand the prevalence of cholera infantum among the very poor, where fresh, wholesome milk is almost unknown.

Not a few medical teachers advise the prohibition of milk during the progress of cholera infantum, basing their opinions on clinical experience. The same view had been reached by the author of the paper through a long series of laboratory experiments, which show that normal milk inoculated with a small portion of poisoned milk and kept a few hours at the temperature of the body becomes itself poisonous.

Dr. Lewis P. Bush, of Wilmington, Del., advocated the use of a young and healthy cow, isolated from others, as in a herd there was a possibility of the contraction of some disease which might injure the milk.

Dr. R. B. White, of Ennis, presented the following rules which his experience had suggested:

1. Test with litmus, and add lime water, if required, before every meal.
2. Limit the amount given in twenty-four hours.
3. Allow only bottles large enough for a single meal, four to six in number; those not in use to be washed in boiling water and kept in an alkaline solution or suspended in the sunlight.
4. The best nursing-bottle is a two- to six-ounce flask, with a rubber nipple drawn over its mouth.
5. Bring the milk to the boiling-point, and then keep it on ice.

Dr. A. E. Goodwin, of Rockford, Ill., was in the habit of insisting on the milk of one healthy cow well fed and stabled, on boiling the milk and keeping it in a sealed glass vessel at a temperature not higher than 60° F., and diluting it with from one-third to one-half of water with, perhaps, the addition of a little malt.

Dr. W. D. Booker, of Johns Hopkins University, stated that there can be little doubt of the injurious effects of micro-organisms upon milk, and the best way to prevent this is not to trust to keeping the milk cool, but to first boil the milk in a flask supplied with a sterilized cotton stopper or a suitable sterilizer. It can thus be set aside and kept for a considerable time in a pure condition.

He believed it was important, in considering the injurious effects of decomposing milk upon children, not to overlook the danger of other injurious articles of food, which we know to be indigestible by children, and which are probably more often the first cause of the indigestion.

The President, Dr. J. Lewis Smith, of New York, asked the writer of the paper in regard to the post-mortem appearances in the animals who had died from the effects of tyrotoxicon, and especially in regard to the mucous membrane, which, in patients dying from cholera infantum, is pallid after an illness of twelve or twenty-four hours, and injected if the disease had lasted three or four days.

Dr. Vaughan replied that the mucous membrane of the stomach and intestines had been, as a rule, pale, and even almost white. In cases where the animal had survived a longer time, the membrane had been congested, but never in a very marked degree.

The President added that, contrary to the opinion of some good observers, he entertained the conviction that the disease is inflammatory in its nature.

Afternoon Session.

Dr. William P. Northrup, of New York, read a paper on

THE PATHOLOGICAL ANATOMY OF LARYNGEAL DIPHTHERIA AS RELATED TO INTUBATION.

In autopsies of children who died after having worn the O'Dwyer tube from three to seven days, there was found merely an abrasion of the superficial epithelium.

This was the invariable rule until the occurrence of an epidemic of measles, in which there were many deaths from complications of pneumonia, scarlet fever, diphtheria, and nephritis. In these children, debilitated by complications, the lower end of the tube thrown against the anterior wall of the trachea, produced instead of the slight abrasions noticed in the other cases, ulcerations, which, in five cases out of twenty-six, exposed the cartilage.

Dr. Northrup summarized his paper as follows:

1. The cases here studied are 116 in number, 90 of which were sporadic, 26 epidemic. They all occurred in the New York Foundling Asylum, an institution which has the constant care of eighteen hundred children from the ages of a few weeks to five or seven years.

2. In the sporadic cases the laryngeal tube of Dr. O'Dwyer caused no ulceration worthy of consideration.

3. In the epidemic cases, numbering twenty-six, there were five serious ulcers.

4. The causes of death have been mostly extension of pseudo-membrane to the bronchi, and pneumonia.

5. I have been able to find *no* evidence that milk or other foreign material has found its way into the lungs. The pneumonia is broncho-pneumonia, and not schluck pneumonia.

A paper by Dr. E. Bouchut, of Paris, France,

ON TUBAGE OF THE LARYNX IN STRICTURE AND IN THE ASPHYXIA OF CROUP,

was read. He reported that in the year 1858, he had tried the effect of tubage of the larynx in a number of children. He had three recoveries in ten cases. He relates one case in detail. The child was eighteen months of age. The symptoms were very serious. The face was livid, and the diminution of sensibility indicated approaching dissolution. A silver cannula was introduced on the end of a sound, with a silk thread attached for extraction. It was coughed up and replaced, and on the sixth day was finally removed, and the child made a complete recovery.

Dr. Joseph O'Dwyer, of New York, read a paper on

INTUBATION OF THE LARYNX.

He began experiments in 1880, at the New York Foundling Asylum. At that time tracheotomy was in disfavor at the Asylum, because for some time its usefulness had not been demonstrated by a single recovery. The difficulty and danger of tracheotomy deter many physicians from the operation, and not a few even of the laity fail to understand how a child's suffering can be relieved by cutting its throat

He first used a prostatic catheter introduced by the nostril. It was found impracticable, partly because the patient would remove it with the hands. The long tube suggested a short one, and its practicability was almost at once demonstrated by the construction of a tube one end of which extended into the trachea, while the other occupied the vestibule of the larynx, permitting the epiglottis to close over it in the act of swallowing. But what was to hold it down in place against the expulsive effort of a cough? First a bivalve form was given to its lower extremity, permitting of its expansion after introduction. But the tube was thus made a trap for fragments of pseudo-membrane. Longer tubes reaching nearly to the bifurcation of the trachea were kept in place better, but after a cough the long tube would be found thrown partially out of place, and had to be pushed back with the finger. A second shoulder was then added to the tube, below the expansion or head at its upper extremity. This shoulder kept the tube from being repelled, but the abruptness of its upper border made extraction very difficult.

The abrupt shoulder then gave way to a gradually tapering enlargement, which was found to accomplish all that could be desired. A tube constructed in this way, when projected upward by coughing, will slip back into position by the pressure of the vocal bands on the sloping sides, aided by its weight. This retaining swell is only made thick enough to hold the tubes loosely in the larynx, in order to permit of their easy expulsion in case of sudden occlusion by masses of pseudo-membrane too large to pass through. Owing partly to this and partly to the difference in the size of the larynx in different children of the same age, they will sometimes be expelled even when unoccupied by false membrane, and before the laryngeal stenosis is fully relieved. If it were not for this, such a tube could be indefinitely worn. A larger and shorter tube would not be expelled, but it would make serious pressure on the lining membrane of the larynx. Such a tube may be temporarily applied with advantage as a laryngeal dilator, not in ordinary severe croup, but in slow cases where little help is required.

Intubation is apparently, but not really, a simple operation. With more than the usual dexterity and coolness, and an easy case, it will be called by the physician who tries for the first time, a very simple thing. With less dexterity and a difficult case to manage, it will be called a difficult operation.

When established, and perfected, and in common use, intubation can never be considered a satisfactory remedy, in view of the complications and the very nature of membranous croup. The first results, if good, will create enthusiasm; if bad, distrust.

In comparing tracheotomy and intubation, the question is not which will save most life in a given number of cases submitted to treatment, but which operation can be performed or will be permitted in the greater number of cases.

A paper was then read on

INTUBATION OF THE LARYNX, ITS ADVANTAGES AND DISADVANTAGES, WITH STATISTICS OF THE OPERATION,

by Dr. F. E. Waxham, of Chicago, Ill. While strongly advocating intubation, the writer would not overlook its disadvantages. The operation is a difficult one in its performance. The soft tissues may be wounded, or the trachea perforated. It is more difficult to extract than to insert the tube. A serious trouble may ensue from the difficulty of swallowing when the tube is in place. These are the dangers. None are so grave that they cannot be overcome.

On the other hand, it has many advantages over tracheotomy. It can be done almost instantly. There is no loss of blood, no pain, no shock, no open wound with the possibility of septicæmia or erysipelas. There is no drying of mucus in the tube, and no necessity for cleansing the tube. Less attention is required in the after-treatment. Finally, we can save as large a number of adults as, and a much larger number of children than, by tracheotomy.

After presenting a series of statistics, the writer closed with the statement that intubation has been performed one thousand times within two years, and that two hundred and sixty-nine lives have been saved from certain death.

Dr. Charles G. Jennings, of Detroit, Mich., expressed high appreciation of the labors of Dr. O'Dwyer and Dr. Waxham, and believed this method to be of great value. His own experience, however, had led him to prefer tracheotomy. His 36 tracheotomies had been followed by 17 recoveries, while he had applied the tube in 12 cases without a recovery. Dr. Waxham's statistics contain about one thousand cases, with twenty-six per cent. of recoveries. He believed that certain operators in both operations have records far above the average, and that the successful tracheotomists have a larger proportion of recoveries than the physicians performing intubation who rank as the most successful. He believed that the personal equation is an important element in considering the comparative value of the two procedures.

Although intubation possesses the advantages alleged

in the papers read before the Section, it remains true that tracheotomy has advantages which should not be forgotten. After an incision the trachea is accessible for the removal of membrane and dried mucus, and direct medication by instillations and powders. Adequate nourishment after intubation is almost impossible, while there is no such difficulty after tracheotomy.

An obvious advantage of intubation is that it can be performed by many physicians who would not undertake a tracheotomy and in this way relief, impossible otherwise, will be afforded in a great many cases. His own experience, however, leads him to urge tracheotomy in all cases offering reasonable chance of success, and to reserve intubation for the cases in which operative interference will give nothing more than euthanasia, and for those patients whose parents refuse consent to tracheotomy.

Dr. T. J. Pitner, of Jacksonville, Ill., questioned the correctness of Dr. Waxham's closing statement that the 249 cases of recovery following intubation were so many lives saved by the operation. This assumes that all cases of stenosis from croup or diphtheria are, without operative procedures, necessarily fatal. He did not, however, question the utility and great importance of this operation, which appears to him to be preferable to tracheotomy.

Dr. Northrup stated, in answer to questions, that in 33 cases he had never met the slightest difficulty in inserting the tube, and had not failed in a single case to fully and promptly relieve the dyspnœa. He had met with no accident, and probably gentlemen present had in the aggregate used the tube several hundred times and had never met with untoward accidents. He thought the only real drawback to the success of intubation lay in its interference with feeding. It is sometimes difficult to keep up full nutrition when swallowing is so impeded.

In one of his cases the physician in charge had retired hopeless, without doing tracheotomy, and being ignorant of intubation. The child was exhausted and comatose. The tube was inserted. The child returned to consciousness. At the end of forty hours he coughed out the tube. It was not reapplied, and the child made a perfect recovery.

Dr. O'Dwyer, in answer to questions, said that, in his opinion, statistics will be of very little value in settling the question between tracheotomy and intubation until a very large number have been obtained. Aside from the question of saving life, intubation will be resorted to in the most hopeless cases, those in which tracheotomy would not be thought of, for the sake of securing euthanasia.

SECTION IN MILITARY AND NAVAL SURGERY AND MEDICINE.

Tuesday, September 6th—Second Day—Morning Session.

The first paper was read by Dr. Robert Reyburn, of Washington, D. C., entitled

Are wounds from explosive balls of such a character as to justify international laws against their use?

The proper discussion of the subject, the speaker said, was largely influenced by the changed conditions of modern, as compared with ancient, warfare. The chief endeavor in the battles of ancient times was to kill as many of the enemy as possible in a given time. The same end is attained in modern warfare; but it has been found that an enemy wounded sufficiently to be *hors de combat* is practically a much greater source of weakness to his comrade than if he were slain in battle. Every wounded man requires the services of at least two able-bodied men for his care and sustenance until he again becomes fit for military duty. The speaker graphically described the characteristic wounds produced by explosive projectiles, which are generally followed by extensive sloughing, which reduces the chances of recovery. Such projectiles were in use during the War of the Rebellion, but were soon abandoned; some thirty-three thousand of Gardner's explosive bullets were distributed during the early part of the war, but were soon withdrawn. During the year 1868, by an agreement made between the principal nations of Europe, at the International Military Conference held at St. Petersburg in October of that year, all the great powers resolved to abstain from the use of explosive projectiles in war under the weight of four hundred grammes. The author concluded by saying that common humanity demanded that the use of such projectiles be prohibited by international law.

A paper on the same subject, by Dr. Charles W. Voorhees, of New Brunswick, N. J., was read by the author, whose opinions were, in the main, those of the preceding speaker. He thought that the wounds produced by explosive projectiles, aside from the great destruction of tissues attending them, were doubtless aggravated by the chemicals to which the explosive properties were due. He did not wish to be understood as advocating child's play in war, but so long as war was a necessary evil, it should be as humane in its methods as possible.

The discussion of the papers was opened by Dr. Marston, of the British War Office, who said that he was not aware that explosive bullets were in use by any civilized nation at the present day; they were in use in India and Africa for the killing of large game, but he had not known of their use since the Crimean War.

The President, Dr. H.N. Smith, of Philadelphia, stated that it was not generally known that the late President Lincoln, early in the year 1863, had issued a notice, or perhaps only a suggestion, that the use of explosive projectiles be discontinued. He was glad to see this question brought before the consideration of the Congress, and as the United States had not been represented at the International Military Congress at St. Petersburg, he advised that the powers be notified through their representatives of the entire acquiescence of the present Congress with the views and agreements then enunciated.

Dr. Jeffrey A. Marston, of England, then read a very able and interesting paper on

Age and acclimatization of soldiers in reference to service.

With regard to age, the author said that a man was best fitted for service, at least in India, between the age of twenty-seven and thirty years. He alluded to the well-known fact that the younger men, although capable of enduring great hardships and privations for a short period, are inferior to adults in their powers of endurance in long-continued efforts.

The influence of climate upon the soldier was discussed at length, the speaker more particularly describing the effects of Indian climate upon the newly arrived soldier. He presented tables showing the mortality among soldiers in Indian service, stating that the prevailing disease among the soldiers is enteric or typhoid fever. This disease may be said to have no geography, extending, as it does, from the Rocky Mountains to the Himalayas. It prevails among Europeans, and is also more frequently fatal during the hot than the cold seasons; according to the experience of Indian surgeons, the greatest period of susceptibility lies between the age of eighteen and thirty years. The liability of death during his first year of Indian service by this disease is greater than by all other diseases.

The British troops suffered greatly in Egypt during the campaign of 1882; in the Soudan campaign of 1884 the troops suffered less from this cause, being daily supplied with condensed water; but in 1885, in spite of this same precaution and of great attention to sanitary details,

for some reason still unaccounted for, the sickness from this disease was excessive.

During the first year of the young soldier's sojourn in India he is likely to be attacked by a fatal form of pneumonia. But of the prevailing affections, next to enteric fever, hepatitis heads the list, this disease being very commonly met with. Cardiac disorders come next in the order of prevalence.

In the discussion which followed, Dr. Morse K. Taylor, United States Army, stated that his experience agreed with that of Dr. Marston in regard to the prevalence of heart affections among soldiers; this fact he thought was not sufficiently recognized by our own surgeons.

Surgeon-General G. T. Langridge, of the British Army, fully endorsed the view of Dr. Marston with regard to the greater power of endurance of the adult men over the younger; these latter, he said, were constantly breaking down while marching, particularly when exposed to the heat. During the Afghan campaign the troops suffered more from enteric fever than from any other disease.

In the absence of their authors, the next three papers were read by title. The first of these, by Sir Thomas Longmore, of Netley, England, Professor of Military Surgery at the Army Medical School, entitled: was "Is it desirable that each Soldier in Time of War, should personally carry a first Field-Dressing for a Wound? If so, is it advisable that a preliminary Wound-Dressing should form part of the Equipment of every Soldier on taking the Field? Of what shall it consist, and in what part of the Soldier's Equipment should it be carried?" The paper was accompanied by a dressing devised by the author for this purpose.

The second paper was by Professor Von Esmarch, of Kiel, Germany, entitled "On the First Provisional Dressing on the Battle-Field," and was also accompanied by a simple antiseptic dressing devised for this use.

The third, entitled "On the Antiseptic Treatment of Wounds in War," was by Dr. M. W. C. Gori, of Amsterdam, Holland.

Dr. John Anderson, of London, read a very able paper

ON HEAT STROKE IN INDIA.

After adverting to the labors of Dr. H. C. Wood, of Philadelphia, upon this subject, he proceeded to a definition of the term heat-stroke, and divided his subject, according to the degree of severity of the disease, into ardent fever, heat, apoplexy, and sunstroke. The first is characterized by a high fever of short duration, and by great exhaustion; the second, by all the signs of apoplexy, and causing death by asphyxia; the third, by great cardial debility and nervous manifestations.

These are all pathologically allied, of course. The speaker briefly alluded to the influence of alcohol in the causation of the disease, which is generally supposed to be due to the direct action of heat upon the meninges of the brain, but the condition of the glandular organs, of that regulator of the heat, the skin, were factors which should not be overlooked.

With regard to the prophylaxis of the disease, protective measures, of course, were all-important, moderate eating, the wearing of thin clothing, and the importance of free ventilation of houses and camps. The author inveighed against the use of alcohol, and stated that the best drink which could be devised for soldiers, while on the march, was cold tea flavored with lime-juice. Regarding the medicinal treatment of cases of heat-stroke, the first indication is to relieve the excessive heat, and for this purpose he had had great experience with the use of a neutral salt of quinine, the hydrobromate, administered hypodermatically in doses of two, three, or four grains, repeated according to indications. The speaker emphasized the necessity of using a thoroughly clear solution, filtered if necessary; when this precaution was taken any untoward symptoms from the use of the needle, other than slight local irritation in some rare instances, were exceedingly uncommon in his experience. As for the occurrence of tetanus as a result of these punctures, he himself had never seen a case of it. The speaker was at a loss to explain the manner in which the quinine reduced the temperature so rapidly in such cases, but thought it probably due to its action upon the cardiac ganglia. After the administration of quinine, the portal congestion usually existing should be relieved by mercurials, and the nervous condition combated by means of the bromides of potassium and ammonium.

Afternoon Session.

Dr. Marston, of England, opened the discussion of the paper by indorsing the view of his compatriot with regard to the efficacy of quinine in the disease, and reiterated the author's cautions in using a perfectly clear solution.

There had been a number of cases of tetanus published in the report of the army in India as due to the use of the needle; such a complication could be avoided by the use of a pure solution and clean instruments. In conclusion, he alluded to the fact that persons who had had sunstroke were thereafter liable to pyrexiæ, without apparent cause. Strong men become nervous and timid, and suffer from insomnia and dreams; they are occasionally subject to neuralgias and excruciating headache after exposure to the sun; he had even noticed, in some cases, paroxysmal attacks of mania. To such sufferers he always advised removal to cooler climates.

Dr. Henry Ernest Goodman, of Philadelphia, had noticed, during the late war, many cases of so-called heat-stroke, in which he almost invariably found some cardiac trouble, sometimes accompanied by a *bruit* at the apex or base; he thought that in these cases the cardiac affection accounted for the heat-stroke, so-called. In his experience during the war, cases of true heat-stroke were exceedingly uncommon.

Dr. Moses K. Taylor, U. S. Army, fully concurred with the preceding speaker in his views, which were in accord with his own observations during the late war.

Dr. Sherwood, of the U. S. Pension Office, spoke of the results of sunstroke as shown by the records of the Pension Office. Many claims have been, and are still received, alleging nervous diseases, such as epilepsy, paralysis agitans, and even locomotor ataxia as the result of sunstroke. He was unable to trace the connection between these diseases. The literature of this subject is exceedingly meagre, and in order to determine the exact relation between sunstroke and nervous affections, if any there be, he enjoined physicians, both civil and military, to keep a record of such cases, and to follow them in their complications as far as possible.

Dr. James Collins, of Philadelphia, expressed the opinion that occipital headache was frequently attributable to sunstroke. For the treatment of the disease he had used quinine, hypodermatically, in a solution of the bimuriate rendered neutral by the addition of a small quantity of urea.

Dr. George T. Langridge, of England, had found the solution of quinine recommended by Dr. Anderson very useful in similar cases—in the Afghan and Boer campaigns, as well as in India. In the latter country, when the disease resisted all ordinary forms of treatment, quinine was almost a specific.

Dr. Eli A. Wood, of Pittsburg, Pa., had found that after removing the clothing the application of ice externally, and even in the rectum, had proved of greater service at his hand than any medicinal treatment.

Dr. Max J. Stein, of Philadelphia, believed that manipulation and rubbing the body with ice produced good results. He believed that a temperature of 111° F., mentioned by Dr. Anderson as necessarily fatal, did not, according to Dr. Austin Flint, always so result.

Dr. W. H. Lloyd, of England, agreed with Dr. Anderson regarding the influence of alcohol in the causation of this disease. His experience in the navy had been that most of the cases of heat-stroke—those occurring on shipboard in the Red Sea at least—were among the cooks, stokers, bakers, etc., who were men of intemperate habits.

Dr. Anderson, of England, author of the paper, thought that no surgeon would neglect the usual means of treatment, but that he had desired to lay special stress upon the hypodermatic use of quinine as the readiest and best means at our command of reducing the high temperature.

SECTION IN LARYNGOLOGY.

Tuesday, September 6th—Second Day—Morning Session.

J. P. Klingensmith, M.D., of Blairsville, Pa., read a paper on

HAY-ASTHMA.

In few diseases does he find so diverse opinions, or so many methods of treatment, as in hay-fever. Dr. W. H. Daly's paper, in 1881, first demonstrated the underlying naso-pharyngeal causes. The exciting cause does not work where nasal mucous membrane is healthy. Must remove the pathological cause before cure can be effected. Dr. Hock, of Freiburg, Germany, had placed much importance upon the pathological condition of the nasal mucous membrane as the fundamental cause. From personal experience, Dr. Klingensmith would place local irritation, hypertrophies, deflected septum, etc., as the starting-point, and dust, pollen, light, heat, etc., as the exciting cause. There must be an abnormal condition before local irritants have power. Always make careful examination of anterior and posterior nares. Radical treatment is called for, especially where there is more or less occlusion. The cautery and Allen or Jarvis' snare will bring about the best results under these circumstances. Sensitive areas he treats by the continued use of acetic acid or cautery. Use cautery at a cherry-red heat; for if too hot one will have hemorrhage follow, and if too cool it will produce greater pain. Once in a week gives time to allay irritation by use of Dobell's solution, etc., before another sitting. Begin treatment at least two weeks before expected attack, and even treat or operate when the disease is at its height. Out of thirteen cases, he cured nine and greatly benefited four.

Dr. Lennox Browne, of London, said that he had heard no new ideas on the subject since the President's paper of six years ago. He does not think that sexual irritation can cause or in any way interfere with hay-asthma, but may do so in nasal troubles. Believes in local treatment and electricity. Dull red heat he likes best.

Dr. E. F. Ingals, of Chicago, Ill., says that it makes no difference whether the electrode is at a white or a red heat as far as hemorrhage is concerned, provided that one does not break the circuit before the wire is removed from the tissues.

Dr. W. E. Casselberry, of Chicago, Ill., agrees that it makes no difference whether red or white heat is used. Cause of disease located in diseased mucous membrane or sensitive areas; must treat several months, till all are removed or destroyed.

Dr. J. MacKenzie, of Baltimore, stated the case of a woman who had been under his care, who always had an attack of hay-fever whenever exposed to the pollen of rose, and even the sight of it would cause a violent attack. He caused a very perfect artificial rose to be made, and one morning when the patient came to the office, entirely free from hay-fever, he placed the rose near by, and in less than a minute her nostrils were occluded, eyes reddened and suffused, and she was in the midst of a bad attack. Air was pure, and there was no dust on the flower.

After having been informed of the trick, fresh pollen put on the flower had no effect, and since then she can use roses without trouble. Sensitive areas are most common on septum; sympathetic and vaso-motor nerves are those involved. Rose- and hay-fever and cough, autumnal fever, and asthma are all the same nasal neurosis.

Dr. J. Solis-Cohen, of Philadelphia: There are too many specialists and not enough practitioners. Lack of equal nerve-tension and action of vaso-motor system upon blood-supply to vessels irritates and predisposes to hay-fever. Treat constitution, and especially nervous system, through interval till next attack.

Dr. Ridge, of Camden, N. J., said he was a victim, and in his case it was hereditary for several generations. Any dust or pollen will cause an attack, and cocaine gives best results in relieving, especially when used in saturated solution of boracic acid (gr. xv. to ℥ j.).

Quite a large portion of the Section acknowledged themselves victims of hay-fever. Inhaling a mixture of the following, acid. carbol., chloroform, camphor, gave the greatest relief in one case. Imagination plays an important part as well.

Dr. Stockton, of Chicago, Ill., gave as causes, (1) highly nervous temperament; (2) diseased air-passages; (3) peculiar external irritants (varies with person). Cold to his head and neck, the doctor said, would cause sneezing for half an hour and other symptoms resembling hay-fever. Could cure for the time, but paroxysms would return.

Dr. Thomas closed the discussion: It is not simply hyperæsthesia, though the nervous factor greatly increases the severity of the attack, and treatment must be constitutional, and especially directed to nervous system.

Afternoon Session.

Dr. D. N. Rankin, of Alleghany, Pa., read a paper entitled

SOME REMARKS ON THE HISTORY OF RHINOLOGY.

Since the nasal cavities play so important a part in respiration, it is surprising that rhinology should have been so neglected in the past. As organs of smell they are to protect lungs from deleterious gases and assist organs of taste, stimulating appetite and even digestion. The reader compared the perfect instruments of to-day with those of thirty years ago, when a tongue-depressor and clumsy polypus-forceps worthy of the village smith had to suffice for many. The art is old; even the Egyptians had some idea of treatment. Professor Czermak, of Pesth, conceived the rhinoscope, after which much was learned of what was before neglected and obscure. Now compare our snares, tonsillotomes, electro-trephines, atomizers, and insufflators. Now local applications can be made to the posterior nares with more ease than formerly to the pharynx. Naso-therapeutics has kept pace, with its list of iodoform, cocaine, rhigolene, resorcin, etc. More advance has been made in the last twenty-five years than in the thousand preceding. It is to be hoped that it will continue. Each country comes in for its own share of the honor due to scientific work, and America is not behindhand by any means. The writer paid tribute to the memory of the late Dr. Louis Elsberg as the father of rhinology and laryngology in America. He also spoke of the successful researches of Dr. Daly, and congratulated the profession on the encouraging outlook for the future.

A special discussion was opened by Dr. E. F. Ingals, of Chicago, on the subject of

EPISTAXIS.

He opened the discussion, he said, for the purpose of bringing out new ideas on the subject, if possible, from others.

Ordinary cases are of no moment, and alarming only in young children and where the system is run down. Severe cases may demand constitutional treatment of ergot, gallic acid, etc., in addition to local applications. Most cases are readily checked by cocaine or tannin. Persulphate of iron is irritating; it causes hard, coagulated masses, beneath which the bleeding continues and which interfere with the use of more effective remedies. Always try and locate the bleeding-point, and cauterize with galvano-cautery, nitrate of silver, iodine, or pure carbolic acid.

In the discussion that followed various methods were suggested for mechanically controlling the hemorrhage, among others packing the nostril with a long, narrow strip of lint soaked in alum, and replacing the same with one moistened with witch-hazel to allay irritation.

Dr. Coomes, of Louisville, does not approve of passing in pledget after pledget of cotton, as he has seen cases where one has been forgotten and caused trouble for years. Counter-irritation over the liver, with mustard-plaster, ammonia, or blister, is very efficacious. The placing of hands or feet, or both, in very hot water is often tried with success.

The successful results from the use of full doses of digitalis in severe cases was quoted to the Section, as was also the employment of a sponge-tent and the domestic remedy of plugging the nasal cavity with a long piece of fat pork passed through to the vault of the pharynx.

SECTION IN PSYCHOLOGICAL MEDICINE.

Tuesday, September 6th—Second Day—Morning Session.

Dr. E. C. Spitzka, of New York, read a paper on

miliary aneurism.

He reported a case which came under his observation in 1886, that of a girl twenty-four years of age, who suffered from insomnia and anorexia and great motor weakness, being scarcely able to cross the room unaided. She had suffered from what appeared to be hallucinations at night for seven years, and during this period it was noticed that from time to time she dropped articles she was carrying. She would often totter and sway from side to side. From March, 1886, she became poorly nourished. Her menses ceased in July, and remained absent until her death. Her brother had also died of a cerebro-spinal disorder, and her father had died at an advanced age with many of the same symptoms. On post-mortem there was found no evidence of softening processes having occurred at any time, although there was found slight grayish discoloration in parts of the substance of the cord.

Dr. Spitzka next reported a case of

deformity of the brain,

with specimen of the cerebellum, in a child aged five. The doctor gave some very interesting details of the anatomical peculiarities, and stated that there was scarcely an organ in the abdominal or thoracic cavities which was normal.

Dr. Savage, of London, England, discussed Dr. Spitzka's first case and cited a somewhat similar one, though without the direct inheritance spoken of in the doctor's. It was that of a lad who developed all the symptoms of disseminated sclerosis—in fact was for many years the stock case in the hospital just as soon as the lecturing season commenced. This case was sent to an asylum. Was excited and maniacal. After six or eight months he lost control over his sphincters, and presented other symptoms that were typical of the disease referred to; and this was diagnosed after his movements and peculiarities had been carefully noted. He finally died, and upon post-mortem examination no insular sclerosis was anywhere visible, neither were there allied changes; there was absolutely nothing present that would indicate insular sclerosis. The doctor said it was now admitted that in cases of nervous disease it is rather the order of the disease than the quality that is worthy of consideration; that a widely spread disease affecting the motor or the general tract, especially the motor tract, will give incoordination, and would give rise to symptoms which in former years would have been attributed to the cerebellum.

Dr. Daniel Clark, of Toronto, read the next paper, with the title

remissions and intermissions in insanity.

He said there can be no vital and psychic energy without its presence and co-operation. It is an indispensable condition. When rigor mortis sets in it takes its flight, hence the evidence of its intimacy with, and necessity to, vitality. It has, in normal physiological operations, seasons of remissions and intermissions, and it determines their intensity and duration in organic life. In chronic pathological conditions the same law exists, but it necessarily, by virtue of low vitality attended with excessive energy, makes the intervals more extended and the symptoms more pronounced in the ever-recurring periodicity and alternations. Dr. Clark treated of a trinity of forces—chemical, psychic, and vital forces—and believed the lower forms embraced the greater.

Dr. Blandford, of London, England, asked Dr. Clark to explain his theory and principle more fully. He differed with Dr. Clark on many points of his paper. He had seen many patients have intermissions of exactly the same form of mental disorder, and who were not subject, as Dr. Clark had claimed, to different forms of mental disease at each remission; and instanced one case familiar to him, of a patient who had been sent to one of the English asylums on thirty-five different occasions, suffering with precisely the same form of mental disorder, mania, upon each commitment.

Dr. Clark stated that his experience had been different from that of Dr. Blandford. He had never seen a patient suffering from *folie circulaire* who enjoyed during intermissions normal mental health. Patients had said as much to him; they had been able to transact business during intermissions, but had lost their former grip on affairs.

Dr. Savage differed quite widely from the sentiments expressed by Dr. Clark, particularly as related to animal magnetism, which, he said, was not at present well defined. The question of the correlation of forces was an important one, and should receive much attention. Dr. Savage cited several cases in which the remissions in *folie circulaire* were complete. He also cited the case of a patient whose disease was diagnosed as general paresis, and who appeared to be steadily going down-hill, but who, after the development of a large carbuncle upon his shoulders, quite recovered, and lived outside transacting business for seven or eight years, when he died of some nervous disease.

Dr. Ferguson next discussed Dr. Clark's paper. He did not believe it possible to explain the rhythmical phenomena of intermissions and remissions of mental disease by Dr. Clark's theory.

Dr. Hughes, of St. Louis, Mo., thought the obstacles which enter into the consideration of Dr. Clark's paper consisted in the barrier which physiology has placed in the way of allying physical organism to chemical organism, and which consists in the basil-motor mechanism and the part which it plays in neuro-pathology and neuro-physiology.

Dr. Clark was glad that his paper had succeeded in evoking discussions upon the subject of the phenomena of remissions and intermissions. He had not assumed that the key presented by him would open the lock. On the other hand, he did not see that the gentlemen who followed him offered any solution of the mystery at all. He believed that when a man suffered from an attack of

insanity a post-mortem examination would, in every case, reveal changes in the brain, no matter whether it was claimed the man had recovered or not. Recovery is only a relative term.

The next paper of the session was by Dr. Horace Wardner, of Anna, Ill., on

OCCUPATION FOR THE INSANE.

The doctor presented some interesting cases from his asylum, upon whom the effect of judicious occupation was nearly marvellous.

Dr. Bower, of Bedford, England, followed with a paper on

OCCUPATION FOR THE INSANE IN ASYLUMS FOR THE PRIVATE CLASS IN ENGLAND.

There had been a change in these asylums since the time Dr. Bucknill had written that they were "castles of indolence," and in his own asylum Dr. Bower had succeeded so well in his plan of insisting upon his patients occupying themselves that he had lost only two patients, who thought honest work derogatory.

The patients have attended to the cows, rabbits, and pigs, and in wet weather have done sawing, some painting, carpentry, chaff-cutting, pumping, and other work not of a menial character. The most suitable work has been copying legal writing. The women sew, knit, do fancy-work, china-painting, etc.; some help the housekeeper to prepare fruit-preserves and puddings. Seventy-five to eighty-five per cent. of Dr. Bower's patients were occupied from two to three hours daily.

Dr. Andrews, of Buffalo, N. Y., said there had been an enormous increase in the amount of occupation by patients in American asylums within ten years. The importance of the subject was now everywhere admitted. Seventy-five per cent. of the patients in the Buffalo asylum are employed, and he believed a like percentage in other asylums. We use moral measures only in inducing our patients to work. We tell them it is for their good, that they are the happier for it, and we rarely have any trouble in the matter.

Afternoon Session.

The first paper was read by Dr. Theo. W. Fisher, of Boston, Mass., on

MONOMANIA AND ITS MODERN EQUIVALENTS.

The doctor gave the nomenclature adopted by various writers and alienists in this country and abroad, and in the course of his paper cited some interesting cases of paranoia which had come under his observation. In Dr. Fisher's opinion there is: First, a common form of primary insanity, with systematical delusions; second, there are many cases secondary to inebriety; third, cases are reported secondary to mania and melancholia; fourth, they occur when no heredity can be proved; fifth, hallucinations of hearing occur in three-fourths of all cases; sixth, episodical excitement is very common; seventh, monomania is the best English term for them; eighth, such cases should be separately classified and reported.

Dr. Walter Channing, of Boston, Mass., next read a paper by Dr. Bannister of Kankakee, Ill., entitled

NOTE ON THE CLASSIFICATION OF INSANITY.

In Dr. Bannister's opinion all the classifications of insanity are necessarily more or less defective. A perfectly scientific or satisfactory one is an impossibility in the present state of our knowledge. The best one, in his judgment, was the clinical or, perhaps more correctly, the symptomatological one. The doctor then outlined in detail such a classification as in his judgment would best serve the purpose.

Dr. Channing then read his own paper on

THE INTERNATIONAL CLASSIFICATION OF MENTAL DISEASES,

which he illustrated with a chart. He said the plan he had brought forward was that sanctioned by the Association of Asylum Superintendents at Saratoga, in May, 1886, and that, in the opinion of foreign as well as American alienists, there should be a classification upon which all could unite. He did not claim perfection for the classification here outlined, but thought it one which would answer the purpose very satisfactorily.

Dr. Yellowlees thought that the classification would not be sufficiently clear. He deplored the fact that, owing to the incomplete knowledge of the subject of mental disease, alienists were still compelled to classify forms of insanity by their outward manifestations. Mania, melancholia, and dementia are simply labels for symptoms. Chronic mania often mixes itself up with dementia. We know what we mean when speaking of mania, melancholia, and dementia, but beyond this the classification is valueless. Primary delusional insanity is not sufficiently truthful, as it often comes after melancholia. One cannot tell oftentimes between primary dementia and the acute stupor of melancholia.

Dr. Duquet did not understand why puerperal mania should be a distinct form in the classification any more than gouty or rheumatic insanity.

Dr. C. H. Hughes, of St. Louis, said that alienists should go forward in their efforts to secure a clear and descriptive classification. Mania, melancholia, and dementia sufficed for courts of law, for jurymen, but science should not be kept down to such a classification from such considerations. The work of inaugurating reforms in classification was a thankless one. Every alienist has peculiar ideas of his own upon this subject, and does not readily incline to those of others.

Dr. Hughes read the next paper, entitled

THE TRUE NATURE AND DEFINITION OF INSANITY,

which was discussed by Dr. Yellowlees and Dr. Channing. A short abstract could give but a faint idea of Dr. Hughes' elaborate and exhaustive essay, which commanded the closest attention. At its close the Section adjourned until 11 A.M., Wednesday.

SECTION IN SURGERY.

Tuesday, September 6th—Second Day—Morning Session.

Dr. John Homans, of Boston, read a paper entitled

THREE HUNDRED AND EIGHTY-FOUR LAPAROTOMIES FOR VARIOUS DISEASES,

a *résumé* of the writer's experience. In these cases he was in the habit of using drainage-tubes, cleaning them once in about four hours; but he did not consider that they drained the abdominal cavity, although Keith, of Edinburgh, has in his possession about two gallons of fluid secured in this manner from one patient. In his own practice, he had had one case of tetanus after laparotomy, the patient dying at the end of six days; one case of stone in the bladder, from hair falling in, forming a nucleus. The greatest number of consecutive recoveries he had had was thirty-eight. He considered that suppurative cysts of the ovary were very rare, only one having come under his notice, and he believed that they did not exist unless exposed to the air or a mucous surface. The removal of sessile tumors was quite a knack, which was only acquired after long experience. The preference of procedure by the writer was the extra-peritoneal, using the wire écraseur, and if the bladder were injured during the operation a soft catheter was retained in the urethra. In five cases of bleeding fibroids, one he had cured, the second relieved in part, and the third received no benefit. Another case, in which the uterus was removed, the patient died. In one case of abscess of the ovary, the patient recovered. The writer called attention to that condition in which fæces exude from the umbilicus through a tube called the "omphalo-mesenteric remains," one case coming under his care. The patient afterward died from marasmus.

One case of tubercular peritonitis he had cured. He had had five cases of artificial anus, with three cures; one case of cystic tumor in which, during the operation and opening of the sac the woman gave a violent cough, and the cyst was forced clean out by the effort. In one case of laparotomy, performed January 27, 1886, the patient was confined in December of the same year. A case of fibroid tumor of the uterus was gradually expelled through the wound in the abdominal wall. The speaker saw no reason why contractions should not occur in this manner as with any other foreign body in the uterus; the removal of uterine appendages in his own practice for nervous diseases had not given good results, only one case being cured; a woman who was very violent during her menstrual period, and who had commenced sexual intercourse at seven years of age, was relieved of her mania, but her mind was weak. He had had two cases of myxo-lipoma, one in a man and the other in a woman; the man died eight hours after the operation. The speaker had performed laparotomy upon him once before, but refused to remove the tumor; the second time the man begged to be relieved of it, and the attempt was made, fifty-two pounds being removed, and other portions were left. He had performed laparotomy once for perityphlitic abscess, and the patient recovered.

Dr. Addinell Hewson, of Philadelphia, presented a paper (which was read by the Secretary) purporting to claim that the main point in laparotomy was the closing of the abdominal wound without sutures. This was done by means of binders' paste and a certain prepared gauze, called

DONNA MARIA'S GAUZE,

and which was first made some forty years ago; this gauze, however, cost $5 per yard. The writer was not partial to wet dressings, and the present paper was reserved to dry dressings.

Dr. I. M. Matthews, of Louisville, Ky., read a paper entitled

WHEN IS COLOTOMY JUSTIFIABLE?

The writer had had twenty years' experience in rectal surgery, and he did not consider colotomy justifiable in cancerous disease of the rectum when located three inches from the anus; again, not in stricture beyond the reach of the finger, nor in aneurism, nor in cases of specific origin. In most of these operations life was not prolonged; he had seen as many live as long without it as with it. The speaker considered the pain in cancer to be inherent. In the division of stricture, he did not consider there was any danger, as the hemorrhage could be controlled. In small ulcers of the gut, he did not believe in operating, antiseptic and internal treatment being preferable, using proper nourishment in such cases. In congenital occlusion of the rectum he did not think it should be recommended, but that the perineal operation should be done. When the sigmoid flexure is blocked the speaker thought it justifiable. The question then arises, What is to be done in the majority of cases for stricture? Linear rectotomy, not colotomy.

The paper was discussed by Professor Dawson, of Cincinnati, O., who quoted a case of cancer of the rectum within reach of the finger; patient suffering fearfully, and upon whom he intended to operate. He agreed generally with Dr. Matthews. He had really never performed colotomy which gave him satisfaction. In syphilitic cases of stricture he had found they could be treated constitutionally.

Dr. Quimby, of Jersey City, asked how nearly the gut was occluded.

Dr. Dawson replied to about the size of the little finger, the edges hard as wood.

Dr. Quimby agreed with Dr. Matthews on this point, and thought there would not be much gained.

Dr. Samuel Benton, of London, England, remarked that if he could get beyond the cancer he performed the operation, but if the growth was high up he performed colotomy. It had not been his experience that colotomy should not be performed in cancer of the rectum; his last case lived sixteen months after; he considered pain was relieved by colotomy. Cases of benign stricture he treated with electrolysis.

Dr. Hamilton, of Columbus, O., gave most rigid cautions against the use of carbolic acid in the rectum, the use of which he could not condemn too strongly.

SECTION IN GYNECOLOGY.

Tuesday, September 6th—Second Day—Morning Session.

Thomas More-Madden, M.D., F.R.C.S. Ed., Dublin, Ireland, read a paper on

THE CAUSES AND TREATMENT OF BARRENNESS.

Few gynecological questions come so constantly before us, and none probably are of greater practical importance, than those connected with sterility, involving, as they do, not merely the physical health of the patient but also in many instances affecting the happiness and welfare of married life. For, at least in the country where his practice lies, child-bearing is still generally, and he believed rightly, held to be one of the chief functions of a woman's conjugal life; while to be sterile is commonly regarded as the protean source of marital troubles.

In this paper will be found, in tabular form, a statement of the causes of sterility in five hundred and twenty-eight of the cases of infecundity which, occurring in married women within the child-bearing period, have come under observation in the gynecological department of his hospital. The cases may be roughly divided into two classes: (1) Those in which barrenness was occasioned by sexual impotency or some physical impediment from the vulvar orifice to the ovaria. (2) Cases of true sterility, or conceptive incapacity from deficiency congenital or acquired, structural disease, arrested developments, supra-involution, etc., of the uterus, or from analogous morbid conditions of its appendages. (3) Cases of barrenness from constitutional causes. (4) Cases in which the causes of infecundity were apparently moral rather than physical, such as sexual incongruity, etc.

According to this table the most frequent cause of sterility is stenosis of the cervical canal. And as he believed the operative treatment of such cases, simple as it is deemed by some, requires more consideration than it generally receives, and frequently proves worse than useless from the disregard of certain details and precautions which he considered essential, he ventured to recommend the use of a method of procedure and the adoption of instruments which he had found advantageous in the curative treatment of stenosis in 380 cases of obstructive dysmenorrhea and sterility traceable to this cause. During the present session 70 cases have been treated in his hospital, and in most he had had the able assistance of his friend Dr. Duke, Obstetric Physician to Stevens Hospital, Dublin.

The essential features of the method of treatment are the separation by cutting and simultaneous forcible expansion of the affected parts, followed by dilatation during the period of cicatrization, so as to prevent their subsequent contraction, and thus to secure the permanent patency of the erst occluded passage. To obtain this result he used three instruments, viz., a special form of uterine director which can, generally speaking, be introduced into any cervical canal, however narrow, and along which a serrated, triangular-guarded knife is made to travel up through the os internum; and, thirdly, a uterine dilator of great power, by which any required degree of cervical expansion may be effectually secured and accurately gauged.

The influence of uterine flexions in the prevention of

pregnancy and the treatment adopted in cases of sterility dependent thereon are next described. So also is the management of aphoria when it results, as is frequently the case, from chronic endometritis. The methods found most serviceable in infecundity due to vaginal, uterine, and ovarian causes are briefly reviewed. More fully dwelt on is the subject of conceptive incapacity from morbid conditions of the Fallopian tubes, as he regarded stenosis, as well as occlusion of those ducts by vaginitis and its results, such as hydro- and pyo-salpinx, far more common causes of sterility than usually thought. He also held that such tubal diseases may often be removed without resort to the serious operative procedures, as removal of the uterine appendages, by some surgeons considered invariably necessary, and by them freely employed in such cases. Therefore he had referred at some length to those less heroic measures, such as aspiration and catheterization of the Fallopian tubes, the feasibility and successful results of which he had clinically demonstrated.

Finally, the question of sterility arising, as it not infrequently does, from constitutional disorders, and instances apparently irrespective of any physical cause, and the method of dealing with such cases, is treated of in his paper.

Dr. S. C. Gordon, of Portland, Me., said he did not believe that cases existed where there was not enough canal for the semen to pass up. He believed with Dr. Madden that vaginismus had very much to do therewith. We must remember that we cannot raise large crops on barren soil. No one has done more for the relief of these conditions than Graily Hewitt, who is now with us. The uterus is in an abnormal position, and you must return it to its normal position, as is his custom to do so effectually with his pessary. Above and beyond this comes the Fallopian tubes and ovaries. The points concerned are, first, vaginismus; second, uterine or pelvic congestion. He was convinced that the Fallopian tubes and ovaries had more to do with sterility than the stenosis of the cervical canal.

Dr. Graily Hewitt, of London, described his method of treatment carefully, and expressed his conviction that the good done was through the straightening of the uterus, not the dilatation. He believed it acted by straightening.

Dr. Lapthorn Smith, of Montreal, thought that in many cases the difficulty did not lie in the vagina, cervix, uterus, Fallopian tubes, or ovaries, but in the testicle.

Dr. Daniel T. Nelson, of Chicago, thought with Dr. Smith that in many cases the male was at fault. If the mucous membrane of the female is pale, anæmic, contracted, cicatricial, containing little blood, the sperm is not nourished, or if so, only for a few days. Sea-bathing often does good, but only when the husband remains at home.

A. Reeves Jackson, A.M., M.D., of Chicago, Ill., read a paper on

THE MODERN TREATMENT OF UTERINE CANCER.

Correct views of pathology and accurate diagnosis form the only rational grounds for proper treatment of disease. The modern treatment of cancer is based on the theory of its local origin, and implies the possibility of its complete removal. If this theory be true, failure to cure depends upon the essential inadequacy of the means used, or their untimely or inefficient employment. All remedial means are inadequate which have not the power to remove the diseased structures. The object of the treatment may be palliative or radical, the determination depending upon the location and extent of the disease and the general condition of the patient. Palliative measures are always available, while radical measures are not always safely applicable. Medical agents taken internally may be beneficial as palliatives, but are useless, so far as we know, in removing or modifying the progress of disease.

Conclusions: 1. Any operation for cancer which does not completely remove the disease will be followed by recurrence.

2. During life the limit of cancerous disease originating in any part of the uterus cannot be known; hence no operative procedure can guarantee complete removal.

3. In view of this fact, no operation is justifiable which greatly endangers life, provided other and safer methods are available.

4. Vaginal hysterectomy is more dangerous, in a certain sense, than the disease against which it is used; that is, a given number of patients afflicted with uterine cancer will live longer without than with the operation.

5. Other methods of treatment, attended by not more than one-sixth to one-fourth the mortality of vaginal hysterectomy, are equally efficient in ameliorating the symptoms and retarding the progress of the trouble, and they have been followed by as seemingly good results as regards recurrence. Hence they should be preferred.

6. Vaginal hysterectomy does not avert or lessen suffering; it destroys and does not save life. It is, therefore, not an useful but an injurious operation, and as such is unjustifiable.

Professor Graily Hewitt, of London, England, read a paper on

THE RELATIONS BETWEEN CHANGES IN THE TISSUES AND CHANGES IN THE SHAPE OF THE UTERUS.

In order to determine more precisely the true relation existing between changes in the tissues of the uterus and changes in its form and shape, concerning which wide differences of opinion prevail, it is evident that the initial stage of these changes offer the widest field for inquiry.

In describing uterine tissue-changes, the term "chronic metritis" is generally employed. It is desired to call attention to a tissue-change sometimes observed on or soon after the arrival of puberty, especially in young women who have been inadequately nourished, consisting in undue softness of the uterine tissues, and associated with them in the beginning of uterine suffering. This undue softness is not "inflammatory" in its nature. It is associated with great flexibility of the uterus, and generally with marked flexion. The author first described it ten years ago, and has repeatedly remarked it since. It has recently been noticed by Dr. Charles D. Scudder, under the term "mollities uteri."

The recognition of the liability to occurrences of this initial change in the uterine tissues is to be regarded as very important in the explanation of the origin and increase in degree of flexions of the uterus. In such cases the uterus being abnormally flexible, the flexion may be easily and gradually intensified by any ordinary exertion, but will be more likely to be much exaggerated and perpetuated by any severe and suddenly acting mechanical disturbance. The process by which the uterus becomes permanently flexed may thus be slow or rapid.

Hardening of the uterus occurs sooner or later. After hardening, the flexion is persistent.

In some few cases the flexion may be persistence of a congenital condition, or due to absence of developmental growth at the time of puberty, without undue softness being present.

In multiparæ a somewhat analogous condition is present, in what is known as "defective uterine involution," the uterine tissues being soft and wanting in resistance. As is generally admitted, slow flexions frequently originate at such times and under such circumstances.

The author contends that the interference with circulation present with uterine congestion is, in most cases, due to association of a weak blood-current and mechanical compression of uterine tissue, due to flexions present in such cases. The uterus being unduly soft, plastic, and mouldable, it takes a flexed shape, which often becomes perpetuated by the hardening process described by Jacobi as the result of chronic metritis. One consequence

of the latter is the presence of sclerosis of the uterine parenchyma. It is to be remarked that the incidents of some of the cases related by Putnam-Jacobi favor the view that the flexion and displacement were operative in producing the menstrual subinvolution, rather than the cervical catarrh, which Jacobi assigns as the principal cause.

As regards endometritis, he considers the condition so described as more generally due to congestive hypertrophy of the uterine lining, and to retained irritating secretion, and that, excluding gonorrhœal and syphilitic cases, the endometritis is secondary rather than primary.

Afternoon Session.

Dr. W. H. Wathen, of Louisville, Ky., read an interesting paper on the subject,

rapid dilatation of the cervix uteri.

The author had learned in the field of experience and observation of the bad results obtained in efforts to dilate the cervical canal by tents, or to enlarge or straighten it by incisions to cure dysmenorrhœa and sterility. He begged to call attention to the more satisfactory means of rapid dilatation with the bivalve or double-bladed dilators now in use, and especially to the substitution of an instrument of his device for Goodell's modification of Ellinger's dilator. If tents were used, he preferred the tupello to any other variety, it being less apt to cause septic inflammation than the sponge, and dilated more rapidly, regularly, and better than the tangle. He referred to endometritis, pelvic hæmatocele, pelvic cellular or peritoneal inflammation, septicæmia, pyæmia, and tetanus, as complications accompanying or following the use of tents, and did not believe that any good results, apparently, were permanently obtained. He claimed the two-bladed dilators are relatively aseptic and are easily used, complete the operation at one sitting, and that the dilatation is comparatively free of immediate or subsequent dangers. It nearly always cures the dysmenorrhœa, and often removes the causes of sterility.

He thought the results of the incision of the cervix up to the vaginal junction, or through the internal os, anteriorly, posteriorly, or bi-laterally, even more unsatisfactory than those following the use of tents. He dilates the cervix in his office, without a local or general anæsthetic, to the extent of half an inch, and allows the woman to walk or ride home a few minutes after. In dilatations of from three-fourths to one inch, he gives a hypodermic of morphia and atropia, then brings the patient under the influence of chloroform before operating. He urges great cleanliness, and all means to prevent septic infection. He uses three sizes of dilators, the largest the one he devised. He explained the points of superiority over Goodell's.

In conclusion, he urged that the operation should not be performed if there is any pelvic inflammation or trouble in the tubes or ovaries; and never, in any case, until we are reasonably positive that the cause of the trouble is in the cervical canal.

Dr. A. Martin, of Berlin, said that the dilatation of the uterus as an operation had undergone remarkable changes since its origination. The instruments shown by Dr. Wathen are an improvement. The great object is to open up the internal os. The degree of dilatation may be required to be less in some cases of small cervix. It is a question whether we have not been dilating in too many cases. He would not recommend that we go back to laminaria- and sponge-tents.

Dr. S. H. Weeks, of Portland, Me., claimed that every case of dysmenorrhœa was not due to mechanical obstruction of the cervix. The ovaries and tubes have much to do with it, and in his experience have been oftener at fault than the cervical canal. He was surprised at the freedom from danger reported in this operation. Professor Goodell has reported one hundred cases with no bad result. These instruments are not devoid of danger, and bad results may come.

Dr. C. R. Reed, of Middleport, O., thought it quite puzzling to the young gynecologist to tell what to do, the testimony being so conflicting. Some authors reported that there never had been any bad results in the few hundred cases that they had operated on; others had frequent fatalities. He had more hesitancy in operating now than formerly. We cannot predict what the result will be in a given case.

Dr. Goelet, of New York, thought that the term rapid dilatation given to the operation was a misnomer. It had come into use to distinguish it from the dilatation by sponge or laminaria-tents.

Dr. Steason, of North Carolina, had performed dilatation fifty or seventy-five times a year, for the past ten years, and keeps his patients in bed but two days. He has never had any fever, and has not used any antiseptic expect soap and water. He uses a glass rod to keep the canal open much the same as does Dr. Goelet, leaving it there sometimes as long as a week. He did not believe in the superfluous use of so much antiseptic.

Dr. A. Reeves Jackson, of Chicago, objected to the operation, because it did not do any good, at least permanent good.

Dr. Hadley, of Australia, never uses sponges and laminaria in dilatation, which he reviewed *in extenso*. He was in favor of the old treatment.

Dr. Harff, of Ohio, recommended an original plan of his own, viz., the use of cornstalk pith. He entered his protest against rapid and extensive dilatation.

Dr. Lawrence, of Bristol, England, had used sounds constantly for years. His patients are constantly coming back. In the unimpregnated uterus, with proper precautions. this treatment can be used but the sound must not be left in too long. He used gelatin-coated sponge-tents, previously saturated with carbolic acid.

Dr. Wathen, in conclusion, as to the question concerning his operating at his office, said he did it without any concern, and no anæsthetic. As to Emmett's opinion, we will concede a great deal to him in gynecology, but he did not see how he could be taken as an authority in this subject, seeing that he has not performed the operation, condemns it *in toto*, and will have nothing to do with it. The happy medium in this, as in other cases, is the thing to follow. No one would dilate for dysmenorrhœa caused by cellulitis or inflammation. The operation can be performed to straighten the neck of the uterus, and we can shorten the neck of the uterus by dilating the cervix and without amputation.

Section in Ophthalmology.

Tuesday, September 6th—Second Day—Morning Session.

Mr. Henry Power, of London, England, presented a paper entitled

microbes in the development of eye-diseases.

After a historical sketch of the earlier researches of Pasteur and those who followed immediately after him, in the discovery of the nature and modes of propagation of microbes, and the demonstration of Huxley and others that diseases were developed by these organisms, and that they would grow and form colonies in especial situations, the reader went over the discovery of the micrococcus of syphilis and the gonococcus of ophthalmia. Chalazion, pterygium, blepharitis ciliaris, purulent conjunctivitis, kerato-iritis, optic neuritis, cerebral meningitis, may be considered to be the result of microbic development. The factors in the production of these effects may be as follows:

1. They may first penetrate into the tissues and use up the pabulum necessary for their growth.

2. They may use up the whole of the oxygen, and so deprive the tissue of a necessary element; or

3. They may throw out what we may call ptomaines, poisonous products.

The essayist related a case of a gentleman who, after a fatiguing walk of some hours, had a sudden accession of pain in the eye and developed an acute conjunctivitis. His opinion was that, though the tissues in a state of health were able to resist the attack of the ordinary microbes, as found in the air of cities and dense populations, when this power of resistance was diminished by fatigue they were able to effect a lodgment and cause disease. He spoke of the experiment with a long tube, coated inside with agar-agar or gelatine, and through which microbic air was passed, showing that different varieties of microbe settled and formed colonies at different parts of the inclined tube, illustrating the fact that microbes were heavy enough to settle, and in different degrees.

The lessons which the author of the paper proposed to draw from this were, to avoid all conditions which may lower the condition of the system, remove the patient from the densely populated parts, and in this connection remember that it has been shown that at sea, at a certain distance from land, the air contains absolutely no microbes. Of course, in crowded ships this condition does not obtain.

Dr. Abadie made a few remarks on the absolute necessity of clean instruments, and cleanliness in regard to all accessories, in eye operations, and was followed by Dr. N. Manolescu, of Bucharest, in the same strain.

Dr. Heyl, of Philadelphia, said that it is evident that two general errors in regard to the subject have been developed. One is, that if a remedy will arrest the progress of the microbe in a gelatine solution, it will be applicable to the diseased conditions produced by that microbe, and also that any antiseptic may be used one for another. The microbe attacks the older and feebler cells in purulent conjunctivitis, and nitrate of silver is of use in destroying these old cells and leaving only the young and vigorous, that are able to resist the microbic attacks. The exacerbations occur as these young cells become older and feebler, and are again cut short by the silver application. Diphtheritic follows closely the purulent form in course and causation in this connection.

Dr. Heyl found the reason for destructive changes in the cornea in these affections in the different application of the epithelial layer to the subjacent tissue. This was also a factor in hemeralopia, the disease being considered as an epithelial mycosis, the palpebral epithelium being lubricating, while the sclero-corneal is intimately connected with the function of vision.

Hypopyon keratitis is an affection of the lymph itself. There has been a solution of continuity and the infection gets into the eye. Thus, also, in cataract extraction the wound lays the eye open to the approach of the microbe. In kerato-hypopyon and abscess a good result was obtained by the use of a salve of agnine having incorporated oleo-resin of cubebs. The application seemed to be quite painful, the patient being kept awake all night by it. A good application is a salve of red cinchona applied on the conjunctiva, right inside of the eye. A great remedy in kerato-hypopyon is the local application of iodoform to the ulcer.

Dr. B. Baldwin, of Montgomery, Ala., hoped that Dr. Power would also present the surgical side of microbe infection, which is now the liveliest question in eye surgery. He wished to present the other side of the case. In cataract operations he used no protection against the invasion of microbes, except to wash the patient's eye and face. In old hospitals it may be as well to wash and use all these precautions, but in new ones simple attention to cleanliness only is necessary. He referred to remarks by Dr. Lister, in a letter to Dr. Knapp, that he thought antisepsis not so urgent in eye surgery, the wound being so small. Dr. Baldwin was doubtful whether any better results were obtained now than before the introduction of antisepsis in eye surgery.

Dr. Landolt, of Paris, France, was astonished to see how little attention is paid to antisepsis in eye operations, and said that we know too little of bacteria in eye affections. His experience was in favor of 1 to 5,000 solution of sublimate in extractions. He saw no objection to the solution. It did not prevent union or damage anything.

Dr. Reynolds remarked that he had not for a number of years had suppuration of the cornea after cataract extractions. He insisted on absolute cleanliness, and where that could not be secured he declined to operate.

Dr. Keyser remarked that the main argument in favor of antisepsis is its success in operations on all parts of the body all over the world. His predilection was for a saturated solution of boracic acid, and he believed that irritation was caused by the mercuric solution.

Dr. Galezowski, of Paris, thought antisepsis necessary in all eye operations, even in chalazion. He had seen in some cases very dangerous results from neglect of this precaution, suppuration of the eyelids, and destruction of part of the cornea.

Dr. E. Smith, of Detroit, wished to speak on both sides of the question. He thought much was due to cleanliness in operations. He dipped his instruments in alcohol, used saturated solution of boracic acid, and 1 to 5,000 bichloride. He believed that he had a short time ago saved an eye by antisepsis when it had been exposed several hours the day after operation in the immediate neighborhood of panophthalmitis.

Dr. Power, in closing the discussion, said that the remarks of some of the speakers had been somewhat away from the subject of the paper as he had intended it. He drew attention to the propagation of pure cultures from kerato-iritis, and the production of the disease in rabbits.

The practice of dipping instruments, etc., in solution of boracic acid was followed by him in St. Bartholomew's Hospital invariably. He was inclined to think that sublimate in the proportion mentioned is painful. Dr. Baldwin's washing he considered to be really antisepsis. He thought Dr. Galezowski's case of suppuration after chalazion operation was exceptional. He very rarely uses a cataract-knife twice, but prefers to get a new and sharp one from the maker for each extraction. Sharpness and cleanness of cut are essential to a good result.

Dr. P. D. Keyser, of Philadelphia, Pa.. read a paper on

OPERATIVE TREATMENT OF SYNECHIÆ POSTERIOR.

He stated that synechiæ were dangerous to the eye, as a rule, in proportion to the firmness of the adhesion. The danger consisted in the recurrent attacks of iritis, caused by the dragging and stretching of the part, resulting in new adhesions, cyclitis, and perhaps atrophy, or sympathetic trouble in the other eye. Of operative procedures, he considered removal of part of the iris not advisable where the centre of the capsule is transparent. After reviewing the various methods in use for breaking up the offending attachments, of which he believed Streatfield's method to be the most successful with a careful and skilful operator, he spoke of their dangers. He objects to Weber's hook, as being too large to manipulate easily and requiring a large opening in the cornea, as well as the other methods with loss of aqueous, which prevents contraction of the iris. He exhibited a delicate modified hook, which he had used with success for a number of years. The method employed is that recommended by Streatfield, and a small opening is made with any cutting needle, affording opportunity of using the hook with as little loss of aqueous as possible. The adhesion having been broken up, atropia is instilled, and a simple Liebreich bandage applied.

Dr. Galezowski remarked the operation was a very

beautiful one, and in many cases afforded good results. He had in five cases of anterior synechia done an operation similar to this, but with a greater hook. The trouble that occurs after is that fresh adhesions are formed, and as well after iridectomy, which may go on to the production of cataract or irido-choroiditis. He had seen in many cases, after iridectomy, lymph exuded and vision destroyed. If the inflammatory action continues, he advised acupuncture and antiphlogistic measures, and when it has subsided, then do the iridectomy, after two or three weeks.

SECTION IN PUBLIC AND INTERNATIONAL HYGIENE.

TUESDAY, SEPTEMBER 6TH—SECOND DAY.

DR. J. A. S. GRANT (Bey), of Cairo, read a paper with the title,

THE HISTORY OF HYGIENE IN MODERN EGYPT,

in which he discussed the methods of hygiene as practised by the Egyptians under the Viceroy Mohammed Ali and under the Khedive Tewfik Pasha, and as influenced by English dominion to this he added some critical remarks and practical suggestions.

Dr. Grant also read a paper,

DENGUE IN SYRIA,

written by Dr. John Montabet, in which, and also from the discussion, it appeared that there was no essential difference as it occurs in that country and in Texas.

THE RELATION OF STATE MEDICINE TO MEDICAL JURISPRUDENCE

was the title of a paper read by Dr. W. L. Schenck, of Boise City, Kan.

DR. RICHARD H. DAY, of Baton Rouge, La., read a paper in which he made

A REPORT OF AN INQUIRY INTO THE FACTS RELATING TO THE EFFECTS OF OVERFLOW OF THE MISSISSIPPI RIVER.

The paper contains facts and deductions obtained by addressing letters of inquiry to five hundred physicians residing in Southern localities. It shows (1) that overflows, as a general rule, are injurious to the public health; (2) that they are more or less injurious according as the inundations are late or early in the season, and whether of long or short duration; (3) that their evil effects upon health are lessened or entirely antagonized by good natural or artificial drainage, and by copious showers of rain occurring during the period of subsidence of the waters; (4) that rice culture is inimical to health only by reason of the improper and insanitary manner of its cultivation; (5) that, as a rule, it is perhaps true that the colored race is less susceptible to the injurious effects of overflows, and of marshy and malarial soils, than the white race. The writer then advises:

First.—The use of rain-water, stored in large cisterns, both for drinking and cooking purposes.

Second.—That all swamp and soils subject to overflows, before being cultivated or settled upon, be cleaned of trees, underbrush, etc., to admit freely the sun's rays and the free circulation of the winds, and that a thorough drainage be effected, so that rapid drying of the soil be not impeded.

Third.—That in the culture of rice, the common plan of keeping the fields covered for long intervals with stagnant water should be avoided, and that, in lieu thereof, frequent irrigation with fresher and purer water should be adopted, the growing crop being supplied thus as often as needed, ditches being so constructed as to let off the superincumbent water rapidly.

Fourth.—That to promote the health of laborers and residents in the river-deltas and lowlands the dwellings should be not less than four feet from the ground, the floors laid tight, and the doors and windows arranged to afford free ventilation, with galleries on all sides wide enough to prevent beating rains from wetting the rooms; that the houses should be erected on elevated ridges, so that water will not settle under or around them; that only a few shade-trees be allowed to grow to break the force of the direct rays of the sun, and all brush and undergrowth be removed, so as to facilitate the free movement of currents of atmosphere.

Finally, the writer advises the importance of rigid cleanliness of person and surroundings, and strict observance of general sanitary rules. The paper further showed that under improved methods of rice culture and management of lands subject to overflows, the frequency and virulence of disease incident to these localities had been notably diminished.

SECTION IN DERMATOLOGY AND SYPHILOGRAPHY.

TUESDAY, SEPTEMBER 6TH—SECOND DAY.

STUDIES IN HIRSUTIES.

DR. G. H. ROHÉ, of Baltimore, Md., read a paper on this subject, in which he directed attention to the theory of natural selection to account for an occurrence of an abnormal development of hair—a reversion of the system to the natural ancestral type. He referred to the work in this field of Dr. Unna, who had shown that the antenatal type of hair, that which falls out soon after birth, is replaced by a stronger, firmer growth, and accounted for the excessive development by the non-occurrence of this natural order. Excessive hairyness in one race may not be considered hypertricosis, when it would be in another. The principal interest for the dermatologist centres in the excessive development of hair upon the face, for which we have a sovereign remedy in electrolysis. The reader went over the histories of the noted hairy persons, giving many interesting facts regarding them. A remarkable feature in these cases is an abnormality in the development of the teeth. Usually only few teeth exist, and Darwin has noted the same feature in abnormally hairy dogs. The suggestion was made that the hairy growth in excess might be a compensation for the lack of dental development. Unna's theory of an arrest of development, though attractive, the author does not regard as proven.

Heredity, usually from the male line, is found in almost all cases in universal hirsuties, and many cases of hypertricosis can be explained in the same way.

He related instances in his own practice where the children of hairy-faced parents also showed beards.

That the appearance of the growth is first noticed about the time of puberty is not singular, for other hereditary traits are developed at this time as well.

DR. UNNA, of Hamburg, regarded the paper as prudent, so far as the pathological portion was concerned. He stated that he upheld his theory, which he had put forth as a more scientific one than other theories which had up to that time been advanced.

He had not been able to study the skin histologically. This is the only way in which advances can be made, and he urged those who have an opportunity to make such studies.

The direction of hair-development changes after birth, and it would be interesting to secure portions of skin to examine for these changes in the different layers of the skin.

It is certainly an hereditary disease, but scientifically this is not a sufficient explanation.

DR. THIN, of London, England, said he had looked upon the disease as due to a deficient physiological development.

There seems to exist a necessary proportion between the length and breadth of the body and the length and breadth of the hair, and any deviation from this proportion constituted an abnormality. The perfect man de-

velops hair in some parts and little in other parts. That hairy persons are strong is a fallacy.

Excessive hair upon the limbs indicates weakness and debility.

An imperfectly developed sexual being will produce an imperfect being.

A hairy lip indicates a woman who will not well carry out the process of childbirth, and he looked upon it as a flag of warning, and thought the removal of the hairs might not be such a great boon to humanity on that account. In bearded females there is a want of sexual differentiation.

Dr. Gottheil asked how the reader would explain the development of hair late in life, relating a case of excessive development of hair at the age of twenty-eight coincident with cessation of menstruation.

Dr. Ravogli, of Cincinnati, O., said that the human race could be divided into classes by the nature of their hair. He had noticed that men have a greater development of hair upon the face and about the ears and nostrils at about the age of forty-five than in earlier life, and he believed that up to this time, or until the skeleton was perfectly formed, the calcareous salts were taken up by the bones, and after this period were appropriated by the hairy growth. If hair be burned we find salts of lime in the ash, and he thinks there is a relation between the quantity of calcareous salts and abnormal growth of hair.

Dr. Reynolds said that the question was an intricate one. He thought it an established fact that there are two forms of hirsuties, one hereditary and one produced by other causes. The deficiency of the teeth was not present in all cases. He had examined one of the hairy men on exhibition in this country and had found the teeth fully formed. He had observed sexual derangement in bearded females, and regarded it as bearing such a causative relation to the deformity as the same condition bears to acne.

Dr. Rohé, in closing, said there were some cases not explicable on the theory of heredity, and he could not explain such cases as that mentioned by Dr. Gottheil. The statement made by Dr. Thin, that excessive hair upon the body should be regarded as a sign of weakness, was new to him, and he was inclined to believe in the popular idea, that the man with plenty of hair upon the body was usually a strong man.

A NEW METHOD OF TREATING DISEASES OF THE SKIN LOCALLY.

Dr. Valentine Knaggs, of London, England, proposed as a substitute for ointments the employment of emulsions which upon drying on the skin form protective films. He had employed these dressings for the past two years with gratifying results in eczemas and other non-specific exudations. The inunction of the body with fixed oils has been found of immense service, but they are not adhesive, and exuding fluids readily escape from the surface. There are two methods of rendering oily substances adhesive: 1. By adding to them resinous, gummy, or alkaline substances. 2. In making use of gums to combine or emulsify a fat with water.

Adhesive preparations, unlike oils, tend to arrest skin-action. Thus tar, varnish, or collodion form an impervious covering. Ointments to which adhesive substances are added diminish skin-action, but do not abolish it.

Well-made emulsions resemble milk or cream, are soluble in watery fluids, and are markedly adhesive, and are made by combining an ointment-basis with water, a vegetable gum, and a suitable antiseptic.

Thus the formula preferred would read:

℞. Paraffine molle	℥ j.
Pulv. gum acac.	gr. 160
Boracic acid	gr. 16
Aquæ	ad ℥ ij.

Stir until emulsified.

Bismuth, zinc, sulphur, or other medicament may be added as desired. Smeared over the skin, a film is formed, which is flexible and protective, and the antiseptics and medicaments have the best opportunity of exercising a beneficial influence.

The author called especial attention to the fact that all lint and textile dressings could be dispensed with. He did not expect these gum emulsions to displace older methods, but that they would serve a useful purpose.

In discussing the paper, Dr. Unna said that we were now in the period of transition, making our annual change of treatment. It was very well for us as specialists to discuss new treatments, but we should not give them to the general practitioner until we were quite sure that they were good, and especially should not confuse him with new treatments until we were quite sure that they were new. He had worked much with fixed dressings and varnishes, and some years ago had described such a varnish as had the reader of the paper. He was glad to confirm the reader's claim regarding the utility of the emulsion-dressing, but could not concede to him that it was new, as there are many other varnishes made with gums and fats. He did not believe that any varnish which is soluble in water can prevent a great amount of evaporation from the skin.

A NEW METHOD OF TREATING THE VEGETABLE PARASITIC DISEASES OF THE SKIN,

by Dr. H. J. Reynolds, of Chicago, Ill. First, the parasiticide must be applied so as to reach the bottom of the hair-follicles in favus, ringworm of the scalp, and barber's itch. The reader proposed to apply the medicament to the diseased part and place over it the positive pole of an electric battery, and the negative upon some other part of the body, and induce the penetration of the solution to the deeper parts by a well-known law of elected physics. He uses a battery composed of a large number of small cells, such as is used for the removal of hairs. The strength of the current must vary with the sensitiveness of the parts—five to fifteen cells, according to the feelings of the patient. Where there is much hyperæmia the current must be weakened. Cocaine, applied in this way, produces anæsthesia of the whole scalp. The surface is first to be thoroughly cleansed. Then saturate the sponge of the positive electrode with the parasiticide solution and place over the diseased patch, and the moist negative sponge over the skin of some other part of the body. A one per cent. solution of the bichloride was the parasiticide employed in the cases reported. He had only had an opportunity to thus treat three cases, but all have been so successful as to give him great confidence in its usefulness.

Dr. Thin said he had been impressed with the great variety of remedies found in literature reputed to cure tinea tonsurans quickly. He regarded the strong solution of bichloride of mercury as dangerous to life, and also likely to cause permanent baldness, although it was the most likely remedy to cure the disease.

Dr. Juler, of Cincinnati, said in cases of favus we usually expect to find a change in the condition of the patient's general health. He regarded it as an extremely obstinate affection, and was inclined to look upon hasty cures as errors in diagnosis.

Dr. Davis, of London, thought that in America skin diseases were more easily cured than in England, from the reports of rapid cures, especially of ringworm and the like.

Dr. Rohé thought perhaps the differences in results were due to the differences in application. He thought the bichloride, in solution of 1 to 1,000, sufficient if applied often enough, before the new spores had an opportunity to be produced. Fully developed organisms resist much less than the spores. So long as one spore remains undestroyed, so long will the danger last. The hyposulphite of soda will destroy, in a short time, the organism of tinea versicolor.

Dr. MacGuire, of Louisville, Ky., said chrysarobin

in gutta percha had succeeded well in sixteen cases of tinea tricophyton recently treated by him.

Dr. Ravogli said if epilation was practised, the parasiticide would reach the spores and the case could be sooner cured.

Dr. Yeamans said the whole matter turned upon whether we can or cannot reach the spores. He believed that it was unnecessary for any case of favus to exist under proper scientific treatment for over four weeks, epilation being practised daily.

In closing, Dr. Reynolds said it was an established fact that cocaine could be applied to the scalp so as to thoroughly anæsthetize the entire thickness of the scalp. Now the question is, whether a parasiticide applied in this way will not act equally well. He thought the electricity might have some influence in destroying the spores.

SECTION IN GENERAL MEDICINE.

Tuesday, September 6th—Second Day—Afternoon Session.

Dr. Josef Körösi, Director of the Communal Statistics of Budapesth, Hungary, read a paper on

THE PREVENTIVE POWER OF VACCINATION,

with a critical review of the vaccinational statistics. After gathering all the different modes of argumentation used up to the present time to attack or to defend the protective power of vaccination, he arrived at the result that the statistical base of these proofs is much weaker than is generally supposed by men of science who could not enter into an examination of the value of the different statistical methods. Even when the direct proof could be furnished, and even when we would find in this way that the morbidity or mortality of the non-vaccinated is the greater one, the anti-vaccinators reply that the whole of the non-vaccinated represents a weaker totality, consisting of the poorer elements, the sick and weaker children; and that this totality is naturally more disposed to get any sickness, but not in consequence of the lack of vaccination, but of the lack of vital powers—an argument which threatens to subvert all vaccinational statistics.

Dr. Körösi shows us that this difficulty can be settled. If we knew what is, for instance, the general lethality (Dr. Körösi distinguishes between mortality and lethality. Mortality is the chance for each living person to die; lethality is the chance for those who are already sick to die. The two notions are widely different but, notwithstanding, often confounded. The mortality of small-pox, for instance, rose to one per cent., the lethality might rise to sixty or seventy per cent.) of the non-vaccinated, we could learn whether their special small-pox lethality is greater; this difference ought to be attributed exclusively to the lack of vaccination. But to ascertain the general lethality of the vaccinated and non-vaccinated people, it would be necessary that the hospitals should state, not only for the small-pox patients, but also for each case of sickness—even the surgical cases not excluded—whether they were vaccinated or not. This innovation was introduced in 1886, at the proposition of Dr. Körösi, in nineteen hospitals of Budapesth and of provincial cities in Hungary. Here the results of the first year's observation, embracing more than twenty thousand cases, showed the general lethality of the vaccinated patients to be eight per cent., and that of the non-vaccinated thirteen per cent.

Thus the assertion of the anti-vaccinators, that among the non-vaccinated the lethality is probably a greater one, is found to be true. But among the small-pox patients the lethality of the non-vaccinated rose to 6.66 per cent; the lethality of the non-vaccinated should thus represent about ten per cent., but in fact that lethality is not less than 49.68 per cent. No doubt it was wrong to regard the whole of this increase (nearly eight hundred per cent.) as the consequence of the non-vaccination. The result is a product of two factors; at one hand of the weaker constitution of the non-vaccinated, and on the other hand of the lack of vaccination. Knowing now the value of one factor, we can calculate what has to be attributed to the other. So we can state that for the non-vaccinated small-pox patients the chance of dying is raised *exclusively by the lack of vaccination* to five hundred per cent.

The same observation made it possible to state also in what degree the morbidity of the non-vaccinated is raised. The result is that the lack of vaccination causes three and a half times more cases of small-pox.

To apply the new method on the mortality, it would be required that at each case of death—and not, as is usual, only at the deaths caused by small-pox—it should be stated whether the person was vaccinated or not. This new regulation has been introduced at Budapesth since 1886; the coroners have to inquire the fact regarding vaccination in each case of death. As also nine other Hungarian cities agree to introduce this new regulation, the observations of Dr. Körösi embrace a population of 717,195 persons. The results of the first year show that the chance to die by small-pox is raised by six hundred per cent. for each non-vaccinated person exclusively in consequence of the lack of vaccination. This new and fruitful method of investigation has finally been applied also to the very important problems of inoculation of syphilis, erysipelas, tuberculosis, etc. In the ordinary way of vaccinational statistics, it is nearly impossible to answer this question. If a man who has been vaccinated in his childhood later gets tuberculosis, how could we know whether his sickness had been caused by vaccination or any other cause? But the new method furnishes the answer. If tuberculosis, syphilis, etc., have been caused by inoculation we ought to find among the vaccinated people more cases than among the non-vaccinated. It is now found that—at least in this first year of observation—there was no influence of vaccination upon syphilis or tuberculosis. But he found that for the children the number of the cutaneous diseases is raised by vaccination, but only by thirteen per cent. Making up now the balance of vaccination and counting its benefits on the credit, its damages on the debit side, it is found that among a population like that of the United States the vaccination would save annually 120,000 lives, while the number of children dying from cutaneous diseases, etc, caused by vaccination, might make 300, so that the balance is an extremely favorable one. The vaccination is an operation, but who would prohibit a life-saving operation where the chances of danger are so extremely few as above mentioned?

Dr. Körösi finished his paper with the remark that after having now furnished direct answers on the protective power of vaccination, we might safely extinguish doubts about the blessings of Jenner's important discovery, which, after the ingenious generalizations of Pasteur, has lost the character of an inconceivable and quite extraordinary appearance, and which must be regarded as one of the most beneficial results of happy empiricism and science.

Dr. C. A. Leale, of New York, expressed himself as greatly interested in the paper, especially for the valuable statistics, evidently the result of so much patient labor. He referred to a commission which had been appointed under his supervision to inquire after the health of the sick children in New York, with the result that there was not a case reported which had had small-pox. This he attributes to the good virus and enforcement of vaccination among all classes.

Twenty years ago he was called to investigate two cases of death alleged to be the result of small-pox, but these were evidently due to erysipelas due to a scratch; this was rendered more positive, as others were vaccinated with the same virus without harm. He once

saw, at the College of Physicians and Surgeons, a child where it was certified that it was suffering from the secondary stages of syphilis due to vaccination.

Dr. W. M. Whitmarsh, of England, inquired what virus was used, humanized or bovine.

Dr. Körösi said it depended upon the physician.

Dr. John Lynch, of Baltimore, said that it was only cranks who will contend that vaccination does not prevent and modify small-pox. Animal virus will always be safe and ought always to be used.

Dr. William Waugh, of Philadelphia, said that statistics ought to be read in the light of personal experience. In a few cases abscesses would occur. He knew of one case of destruction of the eye from the child transferring the matter into it from the arm.

A vote of thanks was extended to Dr. Körösi, and a committee appointed to consider his paper.

Dr. Körösi said that statistics reported against vaccination were greatly falsified.

Dr. W. M. Whitmarsh, London, England, read papers on

VACCINATION AND PASTEUR'S TREATMENT.

He first considered the subject of vaccination, giving a *résumé* of its history from the time of Jenner. He was not in a position, even from a very large experience, to state that vaccination is a preventive against variola, although many believe it to be so. Vaccination does, however, lessen the liability, even though it may not give a complete immunity from disease. Forty years ago sixty per cent. of the people in England were to be seen pitted by small-pox, while at the present day there is hardly one per cent.

In England it is compulsory that all children over three months old shall be vaccinated. Such a law being in vogue, it is the duty of the State to use special care in the selecting of good lymph. This they evidently have not done, the authorities at present depending upon humanized virus, which they dealt out gratuitously to the poor.

That vaccination may transmit disease is conclusively proven in the case of Dr. Cary, who syphilized himself in endeavoring to prove that such a transmission was impossible. Again, there were the instances of the large number of children in Sweden, and the body of soldiers in Algiers, who were similarly infected.

Educate people up to the fact that vaccination, when properly performed, is a good measure, and then their common sense will make them adopt it. During the year ending September, 1885, there were in England 2,806 persons prosecuted for refusing to comply with the law and be vaccinated.

As to how many punctures should be made, and the frequency with which the vaccination should be repeated, there is a variety of opinions. It seems probable that seven years is the longest time allowable before revaccinating.

PASTEUR'S METHOD.

In the paper entitled "Pasteur's Treatment," he reviewed very elaborately the method and principle involved in the preparation of the virus for inoculation. The various instruments used were presented, and their use explained; also a solution, hermetically sealed, containing the prepared virus. Sterilized beef-tea is the vehicle used to contain the virus.

As to Pasteur, he is undoubtedly a first-class scientific chemist, but doubtless he knows little of the art of surgery or the science of medicine. So far as his operations are directed he is constantly changing his methods, thereby showing that he is somewhat doubtful of his stand-points.

It is proved without doubt that dogs shut up in a room and given but a small quantity of water will go mad. In the cases presented and operated upon in Pasteur's laboratory it is extremely doubtful as to whether the patients have had hydrophobia, and consequently it is difficult to determine the curative efficacy of his inoculations. Pasteur originated a disease in rabbits, which he called rabies. It is important, since some of his cases have been fatal, that the disease be not originated by this process of treatment in a person supposed to be, though not actually, suffering from the disease.

There were cases in which Pasteur's treatment had failed, even in a case in which there had been no delay in coming under the treatment.

The only way to settle the question is by the means employed fifty years ago in reference to small-pox, and that was upon convicts, allowing them their choice between their sentence and becoming the subject of experimentation.

It is also necessary to enforce more stringent laws in reference to dogs. They ought to be registered, muzzled, and more carefully looked after by examining veterinary surgeons.

Great credit is due to Pasteur for his earnest labors, and it is to be hoped that, if he has not already, he may eventually make a new discovery.

Dr. C. A. Leale, of New York, expressed his great interest in the papers, and spoke on the latter. As medical officer for several large benevolent institutions for sick children he had coming under his observation from 18,000 to 20,000 sick children annually. These children were sent from all parts of the city, and all were carefully examined by competent medical men. As these children are only the sick ones of the families, they represent the number taken from at least 100,000 children in the city and surrounding places. He had never seen, or had reported to him, a single case of hydrophobia, although hundreds of these children had at different times been bitten by dogs. He had had similar experience in dispensary practice.

He was convinced that much harm had been done by unnecessarily exciting those bitten. It is to be sincerely hoped that the profession will not, with our present knowledge, resort to Pasteur's method of inoculation.

Dr. Wm. Welch, of Philadelphia, Pa., said: I believe vaccination possesses the power of absolutely preventing small-pox. To be entirely free from danger it must be recently and properly done, and under such circumstances he had never seen any bad result. In his hospital experience he had had 5,000 cases come under his observation, and after vaccination he allowed attendants to wait upon the sick patients without their contracting the disease. Humanized virus is preferable, especially such as has been long humanized through several innoculations. It is well, with long humanized virus, to make several innoculations, as virus thus attenuated does not make so profound an impression.

As to durability, it does run out. It was noticeable that among the cases admitted there were no, or very few, children brought in with the disease who had been vaccinated. One of these died.

The dangers of vaccination are two: syphilis and erysipelas—the latter often caused by carelessness on the part of the physician.

SECTION IN OBSTETRICS.

TUESDAY, SEPTEMBER 6TH—SECOND DAY—AFTERNOON SESSION.

Dr. James C. Cameron, of Montreal, Canada, read a paper entitled

THE INFLUENCE OF LEUKÆMIA ON PREGNANCY.

In this he showed, by a *résumé* of the literature, how incomplete our knowledge of the subject still was. We knew that cases were most frequent in women, especially during pregnancy or at the climacteric. Its effect upon the reproductive organs was but little known, and barely mentioned in any work. The disease was apt to begin during the latter part of pregnancy, and indeed, in many of those who became sallow and anæmic during

pregnancy, though only temporarily so, the ratio of white to red blood-corpuscles was much increased.

The case which he reported was unique, in that pregnancy recurred successively during the progress of the disease, and was also interesting in showing a marked hereditary tendency—the parents of the patient and her six children being all leukæmic. The splenic tumor was first noticed during a pregnancy, and increased markedly in size during each successive gestation, the disease running a remarkably chronic course. A fact worthy of note was, that the red blood-corpuscles of a child born when the disease was well marked were in the normal proportion in the vessels of the child, even above the normal in the placental artery, but much diminished in the placental vein, showing that the blood actually lost red corpuscles while passing through the placenta. In the placental sinuses the red globules were fewer than in the general circulation of the mother.

Dr. Charles Warrington Earle, of Chicago, Ill., recalled two cases of extreme anæmia, together with great emaciation, occurring during pregnancy, and which at the autopsies were found to be caused by chronic inflammation of the pancreas, all other organs being normal. The pancreas was white and hard, the microscope showing a great increase in the connective tissue. He thought that this condition might explain some cases of pernicious anæmia, and proposed for it the name of pancreatic anæmia.

Professor A. Charpentier, of Paris, France, read a paper entitled

L'URÉMIE EXPÉRIMENTALE.

In this he detailed the results of certain experiments made by him on the artificial production of uræmia in gravid animals, by the injecting into the blood, at intervals, of urea until it was present in excess. In these cases the death of the fœtus preceded that of the mother, and the quantity of urea in its veins was in excess of that in the mother's. The death of the fœtus was caused by this excess of urea in its circulation.

Dr. William T. Lusk, of New York, thought the paper illustrated a most important point. The explanation of the manner of death of the fœtus was certainly ingenious. He had supposed that its death was due to the presence of carbonic dioxide in the blood of the mother.

Dr. Duncan C. MacCallum, of Montreal, Canada, said that in marked albuminuria, with severe symptoms, we were justified in inducing premature labor, and if the death of the child was apt to occur, as had been shown, it was another strong reason why we should not delay too long.

Dr. Alexander R. Simpson, of Edinburgh, Scotland, read a paper giving the results of his efforts to secure

UNIFORMITY IN OBSTETRICAL NOMENCLATURE,

presenting a schedule showing the proposed changes, and detailing some of the opinions he had received from eminent obstetricians. The subject had been opened at the Eighth International Congress, and he hoped this one would take some definite action in the matter.

After animated discussion a committee, consisting of Drs. Miller, Simpson, Lusk, and King, was appointed to consider the matter, and report on Friday, the 9th inst.

Dr. William T. Lusk, of New York, presented a most scholarly paper on

THE PROGNOSIS OF THE CÆSAREAN SECTION.

If it were proposed to beat out the brains of a living child, the suggestion would be received with horror, no matter how great the surgical emergency might be, and yet, with the child unborn, craniotomy was often done for insignificant reasons. A careful *résumé* of the statistics showed very favorable results, even with the old method, when the surroundings were favorable and the operation was performed with proper surgical skill and accessories. Death was most often the result of an avoidable cause. The reader compared the brilliant results obtained abroad with the mortality attending recent American operations, and thought that a more favorable prognosis could not be expected until we had learned to recognize the conditions requiring the operation before the time when it should be done.

Defective diagnosis was the great bar to progress in this country, and all practitioners should qualify themselves to recognize the various degrees of pelvic deformity. An operator should possess at least a theoretical knowledge of the technique of the procedure, and while it was not desirable that anyone should attempt to perform the section, men capable of doing the operation could usually be found, even out of the larger cities.

The paper closed with a plea for Cæsarean section as opposed to craniotomy, even in pelves with a conjugate of three inches.

Dr. M. Sänger, of Leipsic, Germany, presented a paper on

THE CÆSAREAN OPERATION,

which was read in abstract.

Sänger's operation was to be preferred to the Porro when the child was living and could not be delivered by any other operation, or when the child was dead and could not be delivered by craniotomy or embryotomy, or could be so delivered only with the greatest danger to the mother. Good results could be obtained by the Cæsarean section only under certain conditions and when the operation was performed according to certain approved technical principles. These conditions are: 1. The maintenance of an aseptic condition in the uterine cavity, and, 2, early performance of the operation.

Sänger thinks that the cause of the greater American mortality is delay, and only trying the section when other operations have been unsuccessful. He lays stress on the following:

1. Antiseptic precautions as in other laparotomies.

2. The abdominal incision should be made through the linea alba over the middle of the fundus, about sixteen centimetres long.

3. It is not advisable to evert the unopened uterus, as it requires a large incision, except where the fœtus is dead or there are not sufficient assistants.

4. The elastic ligature is not to be used before the uterus is opened, as it endangers the life of the child, or may incarcerate parts of the child, so that it may have to be loosened at a time when the operator requires his hands for more important matters.

5. Open the uterus in situ, by a frontal median incision; cut through placenta, or push it to one side; extract child by the legs; if head is caught, extend incision upward, to prevent any downward laceration of the uterus. At same time, assistant is to press abdominal walls toward uterus to prevent prolapse of intestines or flow of fluid into the the abdominal cavity.

6. The danger from hemorrhage is not so great as is commonly supposed. By pressure on the inferior segment, and by slight torsion or flexion of the uterus and broad ligaments, the bleeding can be much lessened. Do without elastic ligature if possible.

7. Care must be taken in regard to three points in suturing: 1. Accurate union of the incised surface of the uterus by numerous sutures, whereby a broad and close union is obtained. 2. Avoidance of suture-canals in the uterine cavity. 3. Especially careful union of the serous surfaces. Silk is preferred to silver-wire, because silk can be absorbed. Excellent results can be obtained with catgut prepared in oil of juniper, chromic acid, or mercuric bichloride.

Sänger's indications for the Porro operation are: When the flow of secretion from the uterus is impeded by stenosis of the cervix or vagina, or, in some cases, of tumors of the corpus uteri, myomata, etc. He prefers Cæsarean section where the myomata are retro-cervical

or retro-vaginal, because the removal of the whole mass is then impossible or dangerous and the removal of the uterus does no good. In osteomalacia he prefers the Cæsarean section with removal of the ovaries to the Porro operation. He takes exception to Martin's recommendation to do the Porro operation in cases in which the puerperium becomes dangerous to the patient, as in far-advanced affections of the heart or lungs. He thinks such a case has as good a chance of recovery after Cæsarean section as after Porro's operation.

Dr. W. H. Wathen, of Louisville, Ky., read a paper on

ABDOMINAL SECTION FOR REMOVAL OF THE FŒTUS.

He urged that abdominal section should be done in all cases, instead of craniotomy, where the child was living. Craniotomy was often unnecessarily done. The maternal mortality was not greater in selected cases of Cæsarean section than after craniotomy. In moderate degrees of pelvic contraction we should induce premature labor, if the condition was discovered early. Abdominal section should become an operation of election and not a last resort. The uterine sero-serous suture and careful toilet of the peritoneum were indispensable.

SECTION IN OTOLOGY.

Tuesday, September 6th—Second Day—Afternoon Session.

Dr. T. E. Murrell, of Little Rock, Ark., read a paper on the

PECULIARITIES IN STRUCTURE AND DISEASES OF THE EAR OF THE NEGRO.

By negro was meant the typical African, and not the mixed races. The negro has fewer aural affections than the white man, and for this reason deafness is much less common in this race. His immunity from aural diseases is due to other than accidental causes alone. Peculiarities in anatomy are met with sufficiently striking to explain some of his exemptions. The following peculiarities in the anatomy of the ear and adnexa are more or less conspicuous: The pinna is small, with lack of development above the concha, and is set closely to the side of the head. The external auditory canal is large, quite straight, and of less average depth than the standard. The membrana tympani is large in its diameters, and forms a less oblique angle with the axis of the canal than that usually given. The mastoid process is very slightly developed, and inconspicuous. The pharynx is large and capacious, with great breadth between the fauces. The nares are broad and flared, giving immense breadth to the choanæ. Deflection of the septum is seldom an obstruction to nasal respiration. Diseases of the external auditory canal are mostly accidental and traumatic. Impacted cerumen is less common than in the white races. Otitis parasitica is rare. Otitis media suppurativa acuta is rather frequent in children, but less so than in whites. Rhinitis purulenta is common in strumous children, and in these the suppuration in the middle ear mostly occurs. Recovery generally takes place with little loss to hearing. Otitis media suppurativa chronica is still less common. Mastoiditis is extremely rare. Otitis media catarrhalis chronica is very infrequent.

Deaf-mutism is of much smaller percentage than in the white races. Among the accidental causes of aural affections may be mentioned: The Southern negro lives in open houses, and is therefore less liable to head-colds than otherwise. His colds are mostly pectoral.

The paper gave rise to discussion, and, as the subject was a new one, to diversity of opinions, expressed by Drs. C. M. Hobby, of Iowa City; Robert Tilley, of Chicago; L. Turnbull, of Philadelphia; S. O. Richey, of Washington, D. C.; and George E. Frothingham, of Ann Arbor, Mich.

Dr. John F. Fulton, of St. Paul, Minn., followed with a paper on

PRIMARY INFLAMMATORY DISEASE OF THE MASTOID ANTRUM.

Primary disease of the mastoid cells and antrum is sufficiently common to merit much careful study and classification. Although much of the disease that attacks this region is secondary to inflammation extending from the tympanic cavity or external canal, there can be no doubt that the reverse of this is also true. Acute primary inflammation, either suppurative or non-suppurative, of the pneumatic spaces is extremely difficult to diagnose. The symptoms are obscure and are often referred to parts remote from the seat of disease; therefore a careful clinical history is most important.

The author has known this trouble to be diagnosed as neuralgia, and the patients allowed to suffer for weeks and months, until the trouble has been developed and relieved by spontaneous opening of the cavity's wall. Some of the suppurative cases result in a sub-periosteal abscess behind the auricle. In the present state of our knowledge a positive diagnosis of primary disease of the mastoid cells cannot always be made, as neither the symptoms nor etiology have been sufficiently studied. Pain is the symptom most relied on, but this is sometimes very deceptive, as it frequently is referred to regions of the skull quite distant from the seat of the trouble; it is, however, apt to be constant, "stinging," throbbing, and tearing. The patient gets no rest, the discomfort being much increased at night. A diagnosis is best arrived at by a process of exclusion.

There is no trouble with any other portion of the ear; no dulness of hearing, no tinnitus. The diagnosis is rendered almost certain if a swelling develops itself behind the ear *late* in the attack. Disease of the mastoid cells runs rather a slow course. Those of strumous or syphilitic origin are very slow. As soon as the diagnosis is made the mastoid should be opened, when relief will be almost instantaneous.

Dr. George E. Frothingham, of Ann Arbor, Mich., then read an elaborate paper entitled

INDICATIONS FOR ARTIFICIAL OPENING OF THE MASTOID PROCESS, AND BEST METHODS FOR CLOSING THE SAME.

The two papers were extensively discussed.

Dr. Robert Tilley, of Chicago, Ill., read a paper entitled

INHERITED SYPHILIS AS A FACTOR IN SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR.

He first reviewed the literature of the subject, and then spoke of the acknowledged influence of inherited syphilis in its relation to the middle ear and the membrana tympani. He then spoke of the similarities in development and differentiation between the cornea and the membrana tympani, and asked the question, Why should one be frequently the victim of inherited syphilis and the other exempt from its influence?

Dr. C. M. Hobby, of Iowa City, read a paper on

CEREBRO-SPINAL FEVER AS A CAUSE OF DEAFNESS.

Cerebro-spinal fever occurs very early in life, fourteen per centum of the cases of deaf-mutism thus caused having originated under one year of age among those personally examined, fifty-seven per centum originating under two years of age, one case noted at two months, and five at three months. What would be the percentage if the proper value were given to the record "born deaf?"

Investigation has heretofore been mainly directed to consanguinity and prenatal influences as causes for deaf-mutism, and based upon the startlingly apparent proportion of congenital cases. Reports of from thirty to sixty per centum of cases "born deaf" are acknowledged by many superintendents to be valueless; probably ten per centum will more than cover the congenital cases.

The nasal diseases of infancy are not so operative as has been supposed, a large proportion of so-called congenital cases being due to early intercranial disease.

Diagnosis of cerebro-spinal fever in infancy presents many difficulties. Cases of deafness attributed to scarlet fever have been found without tympanic lesions and without ability to perceive sound either aërially or by bone-conduction.

In eighty-four deaf-mutes, where the deafness was caused by cerebro-spinal fever, sixty-three per centum had absolute loss of hearing in both ears; in about the same percentage no lesion was found in the tympanum by inspection of the membrane.

Blindness after cerebro-spinal fever is usually caused by suppurative choroiditis, but atrophy of the optic nerve, without ocular lesion, occurs (two cases reported). Deafness is probably due in the vast majority of cases to disease of the labyrinth, but occasional lesion of the auditory nerve is probable; coincident paralysis of the facial is at least very rare; sense of taste is sometimes lost or affected. Blindness resulting at the same time with deafness is not very uncommon.

SECTION IN PATHOLOGY.

TUESDAY, SEPTEMBER 6TH—SECOND DAY—MORNING SESSION.

THE PRESIDENT read a paper on

THE PATHOLOGY OF REYNAUD'S DISEASE,

and reported an unusual case.

DR. E. O. SHAKESPEARE, of Philadelphia, Pa., followed with a paper entitled

EXPERIMENTAL RESEARCHES CONCERNING THE INFECTIOUS NATURE OF TRAUMATIC TETANUS.

PROFESSOR HENRY SEWELL presented a paper on

EXPERIMENTS ON THE PREVENTIVE INOCULATION OF RATTLESNAKE VENOM,

which was read by Professor Vaughn, of Ann Arbor, Mich.

DR. DE SOLOMON, of Michigan, read a paper on

THE PRODUCTION OF IMMUNITY BY THE HYPODERMIC INJECTION OF STERILIZED CULTURES.

SECTION IN PHYSIOLOGY.

TUESDAY, SEPTEMBER 6TH—SECOND DAY—MORNING SESSION.

DR. W. D. HALLIBURTON, B.Sc., of London, England, read a paper entitled,

COMPARISON OF THE COAGULATION OF THE BLOOD WITH RIGOR MORTIS.

The coagulation of the blood can be prevented either by cold or by the admixture of certain neutral salts. Kühne was the first to show that cold prevents the coagulation of the muscle plasma of frogs. By means of methods very similar to those employed by that observer, the muscle plasma of warm-blooded animals can also be prevented from coagulating by the same agency. Mixture of the muscle plasma with solutions of certain neutral salts will also prevent its coagulation; and, as in the case of salted blood plasma, dilution of such salted muscle plasma brings about the formation of a clot of myosin; this occurs most readily at the temperature of the body, and is entirely prevented by a temperature of 0° C. It is hastened by the addition of a ferment prepared from muscle in the same way as Schmidt's fibrin ferment is prepared from blood. Rigor mortis is thus the result of a ferment action similar to that which converts fibrinogen into fibrin; but the myosin ferment is not identical with fibrin ferment, as it does not hasten the coagulation of salted blood plasma, nor does the fibrin ferment hasten the coagulation of muscle plasma.

The myosin ferment is either identical with, or closely allied to, one of the proteids of the muscle plasma, which has the properties of an albuminose.

Though it is thus seen there are very striking resemblances between the formation of fibrin and that of myosin, there are also certain differences, of which the most important are the three following:

1. Myosin can be easily redissolved by solutions of neutral salts, and this solution can be made to undergo recoagulation by dilution and addition of myosin ferment. The passing off of rigor mortis seems to be due to a similar reconversion of myosin into myosinogen. Fibrin, on the other hand, cannot be made to undergo such a recoagulation.

2. The formation of myosin is accompanied by the formation of lactic acid. The same acid is formed when the recoagulation of pure myosin occurs, and its source is thus shown to be a proteid one, not a carbohydrate, as some have supposed. Fibrin formation is not accompanied by the development of any acid, so far as we are aware.

3. The conversion of myosinogen into myosin is not accompanied by the formation of another globulin, as is the case in the conversion of fibrinogen into fibrin.

DR. THOMAS W. POOLE, of Lindsay, Ontario, read a paper entitled

THE NECESSITY FOR A MODIFICATION OF CERTAIN PHYSIOLOGICAL DOCTRINES REGARDING THE INTER-RELATIONS OF NERVE AND MUSCLE.

1. He hoped to show, on the highest physiological authority, that muscles of the involuntary class pass into a state of spasm or contraction, not when their motor nerves are stimulated, but when these nerves are cut, or are paralyzed, or dead.

2. That the same is true of the muscular bands of the arterial coats.

3. That the statements given in our physiological works as to the excited condition of the nervous centres in such states as asphyxia, and the theories of Traube and others in explanation of the Cheyne-Stokes' respiration, in which impure, venous blood, loaded with carbonic acid and deficient in oxygen, is assumed to stimulate and excite the nervous centres, are absurd, and have been put forward solely to meet the exigency of an erroneous theory.

4. His thesis entered into what he deemed conclusive evidence that electricity, as employed for physiological and therapeutical purposes, is not a stimulant but a paralyzing agent to nerve-activity, and that the undoubted beneficial effects of this agent may all be satisfactorily accounted for in strict accord with its rôle as a paralyzer.

5. The same applies also to strychnia.

6. The action of the vascular sedatives, aconite, ergot, etc., and the rigidity and subsequent relaxation of the muscles during anæsthesia are amply accounted for on the view presented in this paper.

7. This theory is not an extension of the inhibitory hypothesis of recent physiology.

8. Ample proof is produced that "irritation" and "inflammation" are not attended by excitation of nervous activity, but the reverse; also, that what is called "morbid" nerve-force, as something different from proper nerve-function, does not exist.

9. Even the voluntary muscles pass into a state of spasm or contraction under conditions which may properly be regarded as attended by a deprivation of nerve-force, oftener, perhaps, than is generally supposed, as in cases depending on "irritation," which is a paretic condition rather than one of exalted nervous activity.

10. It is not necessary to his thesis that he hold, or prove, rigor mortis to be a condition of muscular contraction. But this state has not yet been otherwise satisfactorily explained, the myosin hypothesis proving unsatisfactory in that respect.

SECTION IN OPHTHALMOLOGY.

TUESDAY, SEPTEMBER 6TH—SECOND DAY—AFTERNOON SESSION.

The first paper read was by DR. A. MOOREN, of Düsseldorf, Germany, on

THE SIMPLEST METHOD OF CATARACT-EXTRACTION.

He had had an experience of 5,019 extractions since the beginning of his ophthalmological practice in 1855. He had not invented any new instrument. With the progress of antisepsis and anæsthesia, there was less need than formerly of dexterity of manipulation. He regarded cleanliness and disinfection as clearly identical. He avoided the use of carbolic acid on account of its irritant effect. Preparatory to the operation, he washes the whole face of the patient, then instils a few drops of cocaine. Immediately before operating, he washes the everted eyelids with a three per cent. solution of boracic acid. The operation may be done without a speculum. The only instruments necessary are a Graefe knife, and simple forceps to fix the eyeball. The cut is made downward, and the same knife is used to lacerate the capsule through the intact pupil. Fixation should be abandoned when the patient is restless. Deliver the lens by gentle stroking, then remove the speculum, and rub the closed eyelids over the cornea, and wash again with the same solution of boracic acid. Then a light compress is put on, and retained by means of a strip of adhesive plaster, passing from temple to temple. The plaster should not be allowed to remain longer than four days, on account of its irritant effect upon the skin. In high degrees of atheroma it is better to do an iridectomy, as there may be a resulting leucoma. In such cases Dr. Mooren does the combined operation, making the iridectomy upward. In another form of corneal extraction he uses a lance-shaped knife to make the incision and open the capsule. Here he fixes the eye at the lower margin of the cornea. The iris seldom protrudes, and if it does, cut it off. In this form of extraction, if traumatic cases be eliminated, there is scarcely any bad result. He spoke of modifications in procedure, where the cataract has a hard, large nucleus, and of the necessity for an iridectomy where a foreign body was in the lens, to guard against its being brushed off by the iris during extraction and left in the eye.

Förster's method of ripening cataracts for a few years back has been practised by Dr. Mooren. It consists in puncture of the anterior chamber and sufficient rubbing of the cornea through the closed eyelid. The introduction of instruments into the eye is not necessary. These cases, when complicated with choroiditis, require to be treated with great caution. One case required a year to mature, and a second had an extraction of a half clear lens fifteen months after the puncture, while a third failed entirely to ripen. The after-treatment is complete physical and intellectual rest.

In cases complicated with constitutional diseases, of course, general appropriate treatment is necessary.

DR. GALEZOWSKI, of Paris, prefers extraction through a dilated pupil without iridectomy by corneal section. He makes a sclero-corneal puncture and counter-puncture, bringing out the knife so as to form an ellipsoid incision. With the same knife he makes a vertical incision in the capsule from top to bottom. Pressure below without the blepharostat extrudes the lens. The incision is made in the upper half of the cornea. The accidents are (1) hernia of iris after operation; (2) suppuration of the cornea; (3) iritis; (4) secondary cataract. To prevent hernia iridis do not bring the incision too far out toward the sclero-corneal margin. Then do not open the eye too frequently. If opened every day after operation it makes the patient contract the lids and press out the iris. Do not open the eye for perhaps five or six days; only remove dressing to note swelling and condition. To meet the second indication a disk of antiseptic gelatine is introduced into the eye under the eyelids, the lids closed over it, and left so. These disks are permeated with sublimate and cocaine. In three hundred cases only two have had suppuration.

The astigmatism existing after cataract-extraction he accounts for in this way: In almost all eyes astigmatism exists both in cornea and lens, that of the lens correcting or neutralizing the corneal aberration. When the lens is removed this correcting element is lost, so that astigmatism is found where it did not appear before operation. If the capsule is hard or tough it is seized with a pair of forceps, drawn within reach, and cut off with scissors.

DR. N. MANOLESCU, of Bucharest, read a paper on

CATARACT-EXTRACTION WITHOUT, AS COMPARED WITH EXTRACTION WITH, IRIDECTOMY.

In his simple operations he had trouble from prolapse of iris and other complications due to the difficulty of cleaning out the chamber, and he believes the combined operation to be the more reliable, as it lowers the danger from retained matters and iritic complications. He uses corrosive sublimate as a wash, the toothed forceps for removing the anterior capsule, and closes the wound with a rubber spatula. The eye is dressed with a firm close bandage, and he changes it early.

DR. LANDOLT, of Paris, France, remarked that there never will come a time when only one operation will be the best for all cases of cataract. He himself was greatly in favor of the combined operation, and thought it was better rather to seek a fair degree of useful vision than a symmetrical pupil.

DR. ABADIE, of Paris, finds that extraction without iridectomy may sometimes complicate the reparative process, and it may be difficult to remove cortical substance. He reserves the operation for cases that are healthy, fully ripe, and which promise ease of extraction and good recovery.

DR. MARMION, of Washington, said that his faith in iridectomy in cataract-extraction had not been shaken by the arguments that had been advanced.

MR. POWER, of London, acknowledged himself a convert to the operation without iridectomy. Three years ago he had thought he should never change his opinion or method. But cocaine had rendered accidents less likely and given the patient more confidence. He made his incision nearer the sclero-corneal junction than Dr. Galezowski, but agreed with him that the less the eye is looked at the better. A very light compress is to be applied over the eye after operation. If suppuration occur, attend to the general health. In regard to iritis, he did not think that iridectomy was any protection against it. In regard to secondary cataract, he had it occur just as many times without as with iridectomy. If prolapse of iris occurs during the operation, cut it off.

DR. REYNOLDS, of Louisville, Ky., thought that in cocaine and without general anæsthesia we had eliminated the chief sources of failure in cataract-extractions. In carefully selected cases simple extraction might be preferable. In such cases he uses Graefe's knife, and allows the aqueous humor to escape before completing the section, which he makes as nearly as possible in the plane of the anterior face of the iris. In the combined operation he uses Beer's knife. He attaches importance to the way in which the capsule is divided. He makes a flap opening upward, and it frequently tears in other directions. As to eserine after extractions, if the pupil remains large, use it; if small, do not. He never uses fixation-forceps, but steadies the eye with his fingers. He has no use for an assistant in a cataract-extraction. The dressing is a minute film of absorbent cotton, held in place by a strip of adhesive plaster from lower lid to brow, about an inch wide and one inch and a half long, and renewed daily.

DR. KEYSER, of Philadelphia, objected to one operation for all classes of cases. Before the introduction of

cocaine he made the downward section; now he makes the cut upward. He tries to remove a piece of the capsule. He never operates without examining the urine for albumen. If there is albumen he looks out for iritis. He uses a solution of boracic acid, as sublimate seems to irritate the eye.

Dr. J. L. Thompson, of Indianapolis, found that malaria might cause iritis after extractions.

Dr. Baker, of Cleveland, O., concluded that he could not do without an iridectomy. He follows Mr. Wolf's (of Scotland) suggestion, and makes a small iridectomy, leaving a small pupil, delivers the lens slowly and avoids touching the cornea, saving the patient pain after the operation.

Dr. Landolt prefers to make a large iridectomy if he has a large corneal section, and excise as much iris as he can. A small iridectomy is more dangerous than a large one. It allows one to control the field of operation better. He had not had any irritating effect from sublimate solutions in his cases.

Dr. S. M. Burnett, of Washington, has extracted twenty to twenty-five cases without iridectomy, one of black cataract. He thinks there is no form of cataract that cannot be operated on by this method, and there are no more complications than where iridectomy is made. The removal of cortical substance is more difficult without than with iridectomy. He washes out the cortex.

Dr. E. Smith, of Detroit, thought there was no certain operation that could be laid down for all cases. He found that it was not always convenient to do a preliminary iridectomy some weeks ahead, as the patients objected to more than one operation.

Dr. Beaver, of Reading, Pa., asked whether the simple extraction was applicable in weak and flabby corneæ that fell down in wrinkles when the section was made.

Dr. Valk, of New York, has had made an instrument which combines both methods to some extent. He makes a section, then introduces his retracting forceps, which he exhibited, and tucks the iris back out of the way, delivering the lens over the arms of the forceps. The iris is then allowed to fall back to its place, no violence being done it, and giving a perfectly round pupil with no iritis.

The President, Dr. Chisholm, wished that more had been said on the subject of the introduction of antiseptic fluids and eserine into the eye. He submerges the eye in sublimate solution, or one of biniodide of mercury, makes an iridectomy not as large as the corneal section, and simply closes the eyelids and fastens them together with a strip of diaphanous adhesive plaster clear enough to count the eyelashes through, and if no discharge appears leaves it undisturbed.

Dr. Galezowski, in closing, said that he recognized the two classes of cases, in one of which the simple operation was all that was necessary, while in the other the combined operation was the better adapted.

Mr. Power said in regard to antisepsis that he always uses a new knife, and a sharp one, rarely using the same knife for an extraction more than once. He believes the introduction of fluids into the anterior chamber might be dangerous, and he has not seen benefit from the instillation of eserine.

SECTION IN SURGERY.

Tuesday, September 6th—Second Day—Afternoon Session.

The discussion of abdominal surgery was first taken up.

Dr. W. N. Hingston, of Montreal, thought that when any doubt existed as to the course of the bullet, operative procedures were necessary. The speaker considered the paper by Dr. Senn the most able he had ever heard.

Regarding Dr. Homan's paper, he had mentioned that ventral hernia occurred in ten per cent. of his cases; this the speaker considered rather large. Dr. Homan had stated that he had operated for nervous affections in five cases; one was relieved, the other four were not; other professional men had given the opposite result. The speaker remarked that he believed Dr. Homan, but did not believe the others.

Dr. J. B. Murphy, of Chicago, remarked that in regard to the incision being made in the median line, he was in one case compelled to deviate from this rule in order to reach the gut. If the operation is not dangerous to life, he considered it compulsory, and if the bowel is not injured it does no harm.

Dr. W. T. Peck, of Davenport, Ia., remarked that as regards foreign substances in the peritoneal cavity, he had put forty-seven sutures in an ovarian cyst.

Dr. S. C. Gordon, of Portland, Me., stated that out of 80 cases he had seen 3 of ventral hernia; he had operated in 33 hysterical cases, and 25 would say to-day they were cured, which differed from other statements made.

Dr. Cowden stated that he himself suffered from invagination of the gut (referring to Dr. Senn's paper), but the finger inserted into the bowels could just reach it; after days of suffering a long rubber tube was inserted into the rectum, and a large bottle of water secured at the other end and gradually raised; suddenly there was a sharp report and the abdomen was distended. The speaker thought the gut had been ruptured, but the invagination had been reduced, Dr. Senn's proofs upon dogs notwithstanding.

Dr. T. G. Richardson, of New Orleans, remarked that his experience in these cases was that the percentage in the negro was in excess of that in the white man.

Dr. Donald Maclean, of Detroit, Mich., read a paper on

three cases of surgical disease of the kidney, with an account of operations performed for their relief, the complications which arose, and the results.

The first case mentioned was that of a woman, twenty-one years of age, who was supposed to be suffering from an ovarian tumor. Laparotomy was performed. The patient entered the hospital in October, 1884, and in January, 1885, was perfectly well.

The second case was a woman, forty years of age, the same result being secured; all trace of kidney-tissue had disappeared in the immense cyst.

The third case was a child, twenty-two months old; this case resulted fatally.

The next paper, by Dr. Neudörfer, of the Austrian Army, entitled, "On the Present Stand-point of Antisepsis and the Best Mode of its Application in War," was read by title, after which an instructive paper, by Dr. B. A. Watson, of Jersey City, on

the primary treatment of gunshot wounds,

was read. The author first adverted to the requisite qualifications of a military surgeon, and the duties required of him; discussed the selection of a proper site for a field station, and the means which should be adopted primarily for the arrest of hemorrhage. As the ligation of arteries is only, under the circumstances, exceptionally required, compression should be relied on to control hemorrhage. The author urged the importance of removing all foreign bodies from the wounds, and advocated the occlusion of the wounds of entrance and exit with aseptic bandages and compresses. Thoracic and abdominal wounds cannot be treated at the field station, and should be removed from the scene of action as rapidly as possible. Bayonet wounds should be treated in the manner suggested for gunshot injuries, while wounds produced by large projectile fragments of shells, and the like, should receive the treatment usually rec-

ommended for injuries caused by machinery and railroad accidents. The author closed with a few directions for retaining fractured bones in apposition, and the means employed therefor.

The discussion of the paper was opened by an ex-Confederate surgeon, Dr. Cullen, who averred that it was impossible to comply, upon the battle-field, with all the conditions imposed by a strict antisepsis; the speaker spoke of his large experience during the late war, and characterized all attempts of this nature as utterly futile. Rest, he said, was the best primary treatment, and the blood poured out upon the wound was the best antiseptic. Movement was fatal to many cases; the wounded should therefore be as gently handled as possible under the circumstances, sheltered under trees, and kept in a state of immobility.

Dr. William Varian, of Titusville, Pa., spoke of the dressing of a wound in its own blood as a procedure taught to the profession many years ago, and while he recognized the fact that many cases did well when treated in this way, he thought it the duty of the surgeon to treat the wound aseptically, in accordance with modern ideas, as it has been proved beyond a a doubt that such treatment insures a larger percentage of successes than by the time-honored procedure lauded by the former speaker.

Dr. G. T. Langridge, of England, agreed with Dr. Cullen so far as the importance of immobility is concerned. The less a wound is interfered with the better the chance of recovery, but a strict antisepsis is a necessity; the speaker had found that antiseptic wool was a better material for occluding the wound in primary dressing than any other, and is extensively used in the British Army.

Dr. Carnochan, of New York, shared the opinion of Dr. Cullen regarding the primary treatment of wounds in the field, and with him recognized the impracticability of using the antiseptic dressing on the field of battle, although in favor of it in private and hospital practice, where there can be no doubt of its great utility. The soldier himself becomes too indifferent, by reason of constant exposure to danger, to give heed to such details and appliances as the antiseptic treatment demands, so that any dressing designed to be applied by the soldier himself is without practical value.

Dr. L. von Farkas, of Budapesth, then read, in German, a short paper, giving statistics of the results of antiseptic treatment of wounds which were very favorable to the method, and exhibited a form of a drainage-tube and a speculum designed by himself for the exploration of gunshot wounds.

The next paper, by Dr. Eli A. Wood, of Pittsburg, Pa., entitled

THE IMPORTANCE OF THE GOVERNMENT SECURING AND PRESERVING VITAL STATISTICS IN THE ARMY AND NAVY FOR THE BENEFIT OF SUBSEQUENT APPLICANTS FOR PENSIONS,

was read by the author, who emphasized the duty of the Government toward its soldiers and seamen, and alluded to the cost, trouble, and injustice toward applicants for pensions where no complete and authentic records are preserved. He urged that the Pension Office should be so administered that not only individual interests should not suffer, but also to protect the Government against impostors. He enjoined military and naval surgeons to keep a full record of facts pertaining to the clinical history of all diseases and injuries incident to soldiers and seamen.

The last paper of the day, by Dr. Daniel Smith Lamb, of Washington, D. C., on

THE IMPORTANCE OF INTERNATIONAL REGULATIONS FOR THE MEDICAL TREATMENT OF PRISONERS OF WAR,

treated this subject in an able manner. The ancient custom of putting prisoners to death or keeping them in bondage was no longer in vogue. They should be treated, not as criminals—harshly handled or robbed of their personal effects—but as human beings worthy of proper consideration. They should be provided with such food, clothing, shelter, and occupation as will preserve health. If captured while sick or disabled by wounds, or if they become the prey of disease after being captured, they should receive such treatment as will tend to promote recovery. If the captors are unable to afford the proper care or treatment, they should be parolled and returned to their own side, which also should be bound to receive them. It is recommended that this Section of the present Congress give expression to its views and direct its Secretary to notify foreign governments of the same through the legations at Washington.

SECTION IN LARYNGOLOGY.

TUESDAY, SEPTEMBER 6TH—SECOND DAY—MORNING SESSION—CONTINUED.

Mr. Lennox Browne, of London, read a paper entitled,

RECENT VIEWS AS TO THE PATHOLOGY AND TREATMENT OF TUBERCULOSIS OF THE LARYNX.

The tubercular bacilli are generally admitted as a cause of specific laryngitis. Entrance is effected through the air-passages, and they are especially liable to accumulate in the upper parts of the lungs, where there is less respiratory action. The disease is usually secondary to pulmonary tuberculosis, and may be due to infection from the bacilli in the sputa coughed up and inoculating some abraded or unhealthy and irritated portion of the larynx, or the germs may find their way thither through the lymphatic system. The bacilli, like all parasites, act as an irritant, and eventually cause breaking down of the tubercular deposits.

They must have an unhealthy or abraded surface on which to locate and thrive, and are prone to choose some weak point. Whether carried by the air, sputa, lymphatics, or general circulation, cases are recorded of infection through wounds and teeth that have been extracted. The author of the paper quoted cases confirming the same.

The state of the health and the assimilation of food, together with tissue nutrition, have more to do with the development of tuberculosis than have locality or climatic conditions. Not only may we have laryngeal tuberculosis as a secondary infection, but we find cases where it is primary. The laryngeal symptoms may be the first to attract attention, and even become far advanced before pulmonary lesions can be detected. This is confirmed by many observers. The bacilli are recognized in the sputa, there is pain in the larynx, and difficult deglutition.

The larynx presents the specific appearance. We find the infiltration, swelling, and ulcers, but still can detect no pulmonary lesion. There must have been some neglected chronic laryngitis, or some solution of continuity when exposed to the presence of these germs. Cases are reported where these local symptoms have yielded to treatment before pulmonary complications were added, and the patients were discharged apparently cured.

Treatment.—Where the general system is not broken down, or the disease advanced to the lungs, sea- or mountain-air and high altitudes, especially in pine regions, are of vital importance. Oxygen, pure air, and the absence of germs are here more to be relied on than the thermal or climatic agents. Dr. Moore has ceased to advise the inhalation of medicated steam; but prefers oxidizing agents. Inhalations of vapor from turpentine, oil of eucalyptus, and menthol he has used with success.

It is well established that tuberculosis is a blood-poison, as is pyæmia, septicæmia, and the like. Germicides should be used, and benefit will result. He places great confidence in atropine, not only as a sedative, but as

a germicide as well. Arsenic often works in the same manner as does mercury in syphilis. So, also, do the salts of calcium, where there are tubercular deposits. The aniline treatment has not been a success, and the gaseous injections are still on trial. Experiments with sulphuretted hydrogen show temporary improvement, with diminution of the amount of sputa expectorated, less pain, and less distress from persistent cough. Still the permanent benefit is doubtful. This treatment needs careful supervision, and should not be trusted to the patients or their friends. The local treatment of tubercular laryngitis gives the best results, especially where systemic treatment is also employed to maintain health and nutrition. Use cocaine, and employ the galvano-cautery or lactic acid to destroy the deposits and induce healthy healing of the parts.

Where the infections are local, our success is in proportion to their accessibility.

He does not like iodoform or iodol dissolved in ether, as the ether is too much of an irritant, and prefers a brush made with cotton to the spray, in that it coats the surface better and is pressed into folds which are protected from the spray by the spasm of the larynx. The continued use of the spray he considers dangerous to the ciliæ of the epithelial cells. Local and systemic sedatives are emphatically called for. Insufflation is not as good as where emulsions are made with acacia, as it is apt to form cakes. Cocaine gives temporary relief, but morphia, belladonna, and balsam are more permanent in their relief of both pain and cough.

The surgical measures are to scrape away the deposits with curette or forceps, under cocaine, and apply lactic acid. Do not stab or incise; it may relieve tension and congestion, but is bad in that it gives new foci for infection. For the same reason it is better not to remove glomerulata unless respiration is seriously interfered with. Tracheotomy, for the purpose of giving rest to the larynx, is useless, and worse. The larynx does not then receive the necessary air and oxygen, and bacilli-infected mucus accumulates. The cold and dry air irritates the lungs and may induce pulmonary complications. Besides, the wound may become infected. Intubation of the larynx likewise causes too much irritation and aggravates the trouble, independent of the risk of blocking up the tube. Even refrain from removing elongated uvula. He does not approve of the recent suggestion of extirpating diseased portions.

Many apparent cures are reported, and he has had such cases himself, but is inclined to doubt their permanence. We can improve the condition of the larynx, stop pain and cough, cause better assimilation of food, and improve nutrition. There result local relief and apparently satisfactory results, but scarcely a cure, as claimed by Schmidt, Bosworth, and others.

Important suggestions.—(1) Early diagnosis and treatment. (2) Do not be carried away with new remedies. (3) Never be too active in destroying tissue; heal instead. (4) It is better to observe facts and be influenced by the experience of many, than by the new ideas of the few.

Dr. Sinclair Coghill, Ventnor, England, advised to treat more to alleviate pain and distress, which tend to shorten life, and obtain as much rest for the parts as possible. Look to body-nutrition. He also quoted cases of primary tubercular laryngitis from infection. The greatest benefit was from iodoform and morphia by careful insufflation. He had seen cases apparently cured. The medium or tissue in which the bacilli thrive was to him more important than the bacilli themselves. We do not see parasites in vigorous tissues; those well nourished are not liable to infection. Do not trust to local treatment alone, but improve digestion and assimilation.

Dr. J. Solis-Cohen, of Philadelphia said sulphurous treatment improves tissues or soil so that germs cannot flourish as well. He only recalled two cases of recovery from supposed tubercular laryngitis. He scraped andapplied lactic acid, also used morphia, iodoform, and atropia, and believed in them. He condemned tracheotomy to obtain rest.

Dr. E. Fletcher Ingals, of Chicago, finds it difficult to choose between high and low altitudes. High altitudes are injurious where the disease is advanced. Calcium salts are beneficial; so, also, are the chlorides. The use of sulphuretted hydrogen, in his experience, increased pain and other unpleasant symptoms, so he abandoned it. He also had poor results from lactic acid. Morphia, carbolic acid, and glycerole of tannin with water forms an excellent wash or spray. Tannin aids in alleviating pain by hardening the tissues. Glycerole of tannin without water is too irritating.

Dr. Coomes, of Louisville, Ky., finds that iodoform works best, and he uses it extensively for the pain by insufflation after cleansing with Dobell's solution. Whiskey-and-water is excellent to cleanse away the mucus and ease pain so as to allow the patient to eat. He had a bad case where he cured the larynx completely, but the patient died later from pulmonary deposits. He had seen a case recover, even when the epiglottis had sloughed away.

Dr. Devilbiss, of Toledo, O., uses both morphia and iodoform, but with liquid vaseline and sprayed in. He considers the liquid forms of vaseline the very best medium. He uses it with iodine and iodide of potassium.

Dr. Casselberry, of Chicago, doubts the good effect of lactic acid as it causes too much irritation, increases the cough, and does harm. The main point is to cleanse thoroughly, and use morphia and iodoform, or, better yet, iodol, which is lighter and more easily diffused. The temporary effect of cocaine is excellent, but continued use is bad. It causes reaction with congestion, increased irritation and inflammation. Morphia is better, and with iodoform the effect is for a longer time.

Dr. F. O. Stockton, of Chicago, Ill., has not had any success from scraping ulcers, and uses lactic acid, from ten to ninety per cent. He saw a case in Vienna where there were both tubercular and syphilitic ulcerations of the larynx.

Dr. John Mackenzie, of Baltimore, is sceptical as to permanent cures, and thinks that they are more likely diphtheritic cases. He has also doubts as to bacilli, with reference to cause and effect. Why will not they be caught in the nose of the same individual when there is an abraded surface? He is in favor of constitutional treatment and local treatment of bichloride, 1 to 2,000.

Dr. Curtis, of Chicago, says that atropine is of no use. He sprays the larynx with nitrate of silver, with the result of healing the ulcers.

Dr. Browne closed the discussion. He believes in the bacillary origin of the disease, but treats both bacillus and tissue as well. Note the close relation of bacillus of tuberculosis to that of lupus. We must treat individual cases differently. He has had no good results from large doses of quinine, as it was not assimilated. Iodide of potash proved harmful, by causing weight and interferance with nutrition. It is of benefit only in syphilitic laryngitis, which can readily be mistaken for tubercular.

Afternoon Session—Continued.

For special discussion a paper was read, entitled

RECURRENT HEMORRHAGES OF THE UPPER AIR-PASSAGES, BY WILLIAM PORTER, M.D., ST. LOUIS, MO.

Laryngeal hemorrhages are immediately dangerous only when beneath the mucous membrane, when they produce a hemorrhagic œdema and impending asphyxia. Laryngeal hemorrhage is very easily mistaken for hæmoptysis, but on auscultation we can discover no pulmonary signs. A list of the causes of hemorrhage from different parts of the upper air-passages was given, with both medicinal and mechanical treatment of each.

Dr. Stockton, of Chicago, gave the history of an actress who consulted him with reference to coughing up

a considerable amount of bright, frothy blood, which apparently came from the lungs. Examination revealed a small pulsating vessel on the right ventricular band, from which there was a slight spurt of blood at each pulsation. After failing to control it with iron, tannin, etc., the vessel was destroyed with electro-cautery.

Dr. Lennox Browne said that it was usually found in connection with syphilitic or tubercular larynx, sometimes caused by intemperance, and may require general treatment as well; straining of the voice may cause a congestion and dilated vessels. In alcoholic cases we frequently find such patches at base of the tongue, and above epiglottis.

TREATMENT OF LARYNGEAL PAPILLOMATA.

Dr. W. E. Casselberry, of Chicago, read a paper with this title.

The treatment resolves itself into the best methods for removal. Forceps, cautery, curette, or a combination. For small tumors forceps are most commonly used, and are best in that they are simplest. For larger tumors they are bad, for the reason that only small portions can be removed at one sitting, and it will have regained its former size before the resulting inflammation will have been sufficiently reduced to admit of another operation. Case related to illustrate this, where the tumor was afterward extirpated by galvano-cautery. In another case there were a large number of small tumors returning as fast as removed. He had to resort to curette and follow up with cautery. *Sarjous'* electrode exhibited, also handle with light wires attached to the centre instead of the end. Has had excellent results with the cautery. Uses curette and cauterizes bases.

Dr. J. Solis-Cohen, of Philadelphia, uses sponge for small papillomata, especially when below or upon vocal cords. He operates through crico-thyroid membrane for larger ones. Has not found cautery so successful; only scorches mucous membrane, and there is danger of injury to other parts. Believes in crushing with forceps if he cannot remove.

Dr. Ingals advocates using chromic acid on probe and carefully destroying with that agent.

Dr. Lennox Browne for twenty years used sponge, but now prefers the snare. Gave up sponge because he once lost the end of the applicator in the windpipe and *legal complications* developed therefrom. Prefers safe cotton brush with solid and jointless whalebone applicator. For persistent hyperæmia enjoins continued silence and uses lead coil over the larynx. He kindly drew a diagram showing the situation and size of the papillomata in the throat of the Crown Prince of Germany.

It was nearly the size of a split-pea, and situated on the vocal cord, close to its junction with the arytenoid cartilage, apparently having its base partly in the ventricle. What now worries Dr. Mackenzie is not that it may be malignant, but the persistent laryngeal hyperæmia. His work in Berlin was accomplished with strange instruments, and not well suited for the purpose. He found that the surgeons there had decided upon removing one-half of the larynx.

Dr. C. Slover Allen, of New York, gave the history of a case operated on for large papilloma below vocal cords. It was so large as to almost completely close the trachea. There was great dyspnœa on slight exertion, frequent severe choking spells at night, and extensive loss of weight. As tumor could not have been forced through the larynx, even if severed, it was removed through free opening in crico-thyroid membrane. It was taken off by snare, then the base thoroughly extirpated by curette and cauterized. Attachment was just below anterior extremity of left vocal cord. There was no preliminary tracheotomy. Result was complete restoration of voice and health.

Dr. Casselberry, in closing discussion, said that he used twenty-five per cent. cocaine, and had no difficulty in controlling the amount of destruction by cautery. He pressed electrode well into tumor before making the circuit. Had not found the cautery fickle; unsatisfactory results from crushing.

Next in order was a paper for discussion, entitled

THE DIAGNOSTIC DIFFERENTIATION OF RECENT TUBERCULOSIS, SPECIFIC AND RHEUMATIC LARYNGEAL DISEASES,

by Dr. E. L. Shurly, of Detroit, Mich., who gave an abstract of the paper, which can be best shown in tabular form:

Laryngeal Phthisis.	Syphilis.	Rheumatism.
	Hyperæmia or Congestion.	
Occurs later, but not marked.	Always persistent and extended.	Always present; not intense; often localized.
	Tumefaction or Infiltration.	
Constant and peculiar; affecting arytenoids.	Not marked.	Rare, except arthritic arytenoid joint.
	Condylomata and Gummata.	
None.	Sometimes.	None.
	Hemorrhage.	
Rare, as result of erosion.	Very rare.	Common.
	Mobility.	
Slightly affected.	Slightly affected.	Excessive in arthritic.
	Ulcerations.	
Common, develop slowly, scattered, small, irregular, or oval, usually on epiglottis and arytenoids.	May be rapid, but rare; in larynx, solitary; symmetrical and with areola.	None.
	Hoarseness.	
Present.	Slight; also slight dysphonia.	Present; also dysphonia or aphonia.
	Dysphagia.	
Only when epiglottis and arytenoids are affected.	Not marked, unless pharynx involved.	Persistent and constant.
	Pain.	
Absent in larynx.	Absent.	Constant, and about neck.
	Expectoration.	
Often contains bacilli.	Mucus.	Slight.
	Cervical Glands.	
Not enlarged.	Enlarged.	Not enlarged.
	Sensation.	
Not perverted.	Not perverted.	Often perverted; paræsthesia; frequent spasm; also chorea.

CHRONIC RHEUMATIC LARYNGITIS.

Dr. E. F. Ingals, of Chicago, Ill., read a paper on the above subject. It has been recognized for several years, but never thoroughly studied. Had found but few cases mentioned in literature; cases are rare, and usually associated with rheumatic diathesis. Had seen cases where hyoid bone and posterior part of larynx presented the only evidence of the disease. More often with attacks of articular rheumatism. It is erratic and obstinate. Pain may disappear for a few days and then return. In no case is the pain very severe. Hoarseness and aphonia are marked. Pain worse in damp or wet weather, but varies from day to day. Larynx alone may be invaded, or base of tongue and hyoid. Some cases slightly swollen, others not. There may be distention and swelling of arytenoid joint. Diagnose by excluding neuralgia, phthisis, and syphilis. Often confused with neuralgia when no swelling appears. May last from two months to a year or more, with periods of immunity. Ultimate recovery, though one case lasted four years.

Treatment.—Cleansing and astringent spray. Salicylate of soda, iodide of potash, alkalies, oil of gaultheria, ext. phytolacca, etc., used with benefit. During the dis-

cussion that followed, several mentioned cases where they had been puzzled as to the diagnosis, and which could probably have been classed under this head. They would expect to find evidences of rheumatism elsewhere. The subject should be worked up.

Dr. A. B. Thrasher, of Cincinnati, O., read a paper on

RESORCIN IN THE TREATMENT OF NASAL CATARRH.

Resorcin has a great affinity for oxygen, and absorbs it from the tissues; reduces congestion and inflammation by contracting the vessels. In hypertrophic catarrh, contracts turbinated tissues and this effect lasts a long time. Cocaine is only temporary in its action. Good results in infectious skin diseases because antiseptic; penetrates skin and kills germs. Cocaine interferes with secretion and proper functions of mucous membrane. Resorcin gives same results, but normal functions remain. It is slower in action and more lasting in result than cocaine. Cleanse nose with boracic solution or Dobell's, and use two to ten per cent. in vaseline or cosmoline; use a spray every second day. For patient's own use give two to four per cent. It will cure where there are dilated turbinated tissues in from two to six weeks. Allays all redness and congestion. Turgescent state yields better than where true hypertrophy exists.

GENERAL MEETING.

WEDNESDAY, SEPTEMBER 7TH—THIRD DAY.

Dr. Durante, of Rome, Italy, one of the Vice-Presidents, occupied the Chair.

Dr. Mariano Semmola, of Naples, Italy, delivered a general address on

BACTERIOLOGY AND ITS THERAPEUTIC RELATIONS.

The object of medicine is to cure disease. To cure diseases we must know the causes that produce them. The external causes are visible and tangible, but to discover the internal, invisible causes is the aim of medical science. To solve this problem we must employ the true method of solving all problems—the experimental method. Doctors lost themselves in fantastic speculations before this method was known. The wonderful progress of physiology has been made in the light of experimental methods. When morbid conditions had been studied, instead of going on with the same careful and slow research, physicians wanted to hurry on, because they wished simply to cure the sick. To apply the experimental method and, at the same time, go fast is, in the nature of things, impossible. Thus it happened that while physicians were making experiments in the laboratory, instead of having patience to master their studies, they came at once to a conclusion. New hypotheses had to be made, and without knowing it they began again the same errors that had characterized the medicine of an earlier day. New systems thus came into the field, that were the opposite of the experimental method. If medicine is to progress and be a science, it must not leave the experimental method, otherwise there will be nothing but renovations of error and loss of time.

THE ERROR OF THE DAY

is bacteriology considered as the key to all pathology. Bacteriology should be studied, because it teaches what is in the microscopical world, of which we had never dreamed the existence—a world in which man lives, and which is filled with

ENEMIES OF MANKIND.

We drink millions of microbes in water, and respire millions in the air. Sometimes these microbes affect us—perhaps killing in a few hours.

When we strive to cure the sick, we must proceed cautiously, because, before there has been a careful demonstration, if we attempt to deduce a remedy, there is danger of doing harm to the sick instead of curing them. This is the great harm modern bacteriology does. Doctors concluded at once that microbes were the cause of disease, whereas, in many cases, microbes are but

EFFECTS OF DISEASE.

We ought to reproduce the disease artificially by a microbe before concluding that it is the cause. The experiments made have not given any satisfactory results, except in carbuncle and tuberculosis. To conclude hastily that this or that microbe is the cause of any disease, is but to ignore or set aside the experimental method. The demonstration which the experimental method demands in this case would be complicated, because we would not only have to know that the microbe existed, but we would have to know what was the condition of the blood necessary to the culture of that particular microbe, and science tells us that, for the present, this is a problem we cannot solve.

We know very little of the normal condition of the blood, and biological chemistry is still in its infancy. Man cannot separate himself from these millions of parasites among whom he lives. That bacteriology may be a guide in the cure of disease, we must not only learn all we can of the microbe itself, but, more important than all, must ascertain all that is possible of the conditions of the field of culture. The science of the present knows nothing of the conditions of these fields of culture in living organisms. It is thus evident that in the present condition of bacteriology it cannot be taken as a guide for the treatment of internal diseases. The older schools of medicine spoke of organic dispositions, or tendency to such and such a disease. This expression had no meaning, but it expressed the fact. When bacteriology speaks of a need for a special field of culture it says the same thing, because we do not know of what the field of culture consists. Therefore this cannot be called a science, because a science is never composed of unknown things; it goes from the known to the unknown. If a man supposes a fact instead of demonstrating it, the phenomena of nature are not reproduced. When he resorts to hypotheses the power of man disappears. If nature's laws are not respected, the telephone does not work, the electric light does not flash, the steam-engine stops. The doctor, then, is the only one who pretends to become the master of nature without knowing her laws. Referring again to the failure of medicine to follow up a discovery in the scientific way with thorough research and demonstration, and its tendency to accept conclusions quickly, Professor Semmola said that modern bacteriology may lead the way to the most fruitful field of inquiry in the future, but for the present it has produced no practical results in the cure of internal diseases. It has not, he claimed, been demonstrated in what measure microbes are the causes of diseases. He therefore hoped that the younger generation would continue experimental researches with the thoroughness of method which the great masters have transmitted to us. They must renounce their preconceived ideas in medicine, and interrogate nature without torturing her. Scientific independence must be preserved. They must not proceed without measuring their steps. He trusted that his desire for scientific independence in such researches would be echoed in this land of independence.

A unanimous vote of thanks was extended to Dr. Semmola for his address.

SECTION IN THERAPEUTICS.

WEDNESDAY, SEPTEMBER 7TH—THIRD DAY.

Alfred S. Gubb, F.R.C.P. (Lond.), M.R.C.S., of London, England, was elected French secretary.

RHAMNUS PURSHIANUS.

Dr. John E. Brackett, of Washington, D. C., gave a botanical and chemical description of rhamnus purshianus, or cascara lagrada. He considered the fluid

extract, given twice daily in doses of five to fifteen minims, to be curative in chronic constipation, but the conditions favoring the occurrence of the constipation should also be corrected.

Dr. Murrell, of London, England, did not consider that the claims for special virtues in this drug had been well supported. He did not regard it as superior to the other varieties of rhamnus.

Dr. Phillips had obtained such results in chronic constipation that he had been much pleased with it. He had found points of superiority to both senna and rhubarb.

Dr. Woodbury said that in many cases of hemorrhoids accompanying constipation he had found both conditions disappear simultaneously under the effects of cascara, especially in cases of women who are liable to suffer with these disorders.

Dr. Ralph Stockman, of Edinburgh, read a paper entitled

ON THE PHARMACOLOGY OF SOME BODIES DERIVED FROM MORPHINE.

The experiments were conducted jointly by D. B. Dott, F.R.S.E., and Ralph Stockman, M.D. The relationship between chemical constitution and physiological action must always be a subject of deep interest to pharmacologists. In this short paper they proposed to mention briefly the changes in action resulting from various modifications in the constitution of morphine.

How, in 1854, by acting on morphine with methyl iodide, obtained a body which he named hydriodate of ethylmorphia, and which he regarded as a substitution product, the methyl iodide being supposed by him to replace one of the hydrogen atoms in morphine. In the light of our present chemical knowledge we regard How's body as an addition product, iodide of methyl (CH_3I) being simply tacked onto the morphine molecule.

In 1869, Crum Brown and Fraser investigated this body among others, and showed that the original action of morphine is quite lost, and a curare action substituted in its stead. From their nomenclature there can be no doubt that these observers regarded such bodies as addition and not as substitution compounds. Notwithstanding this, we find that in all text-books and reference-books these substances are always named and described as if they were substitution and not addition bodies. It is at present generally held that the substitution of methyl for hydrogen in an alkaloid causes the latter to act like curare, no matter what its original action may have been. The addition products, however, are very different in action from the substitution products.

The formula of morphine is $C_{17}H_{17}NO_3(OH)_2$, and it contains, therefore, two molecules of hydroxyl. It is the hydroxyl-hydrogen atoms which are replaced most easily by alcohol radicals. With regard to the action of morphine it may be divided into two stages—(1) narcosis succeeded by (2) tetanus. Methylmorphine, $C_{17}H_{18}(CH_3)NO_3$, is morphine in which one H has been replaced by CH_3. Codeine has the same constitution, and this body is simply codeine prepared artificially from morphine. The action is exactly the same as that of codeine derived directly from opium.

Ethylmorphine, $C_{17}H_{18}(C_2H_5)NO_3$, has the same action exactly as methylmorphine.

Acetylmorphine, $C_{17}H_{18}(C_2H_3O)NO_3$, and diacetylmorphine, $C_{17}H_{18}(C_2H_3O)_2NO_3$, have a similar action to the two preceding bodies. That is, they produce narcosis in very small doses, which is followed by tetanus when larger doses are given. All these bodies are much more active than morphine, and smaller doses are required. In dogs, however, they produce much greater distress and much more marked vomiting and diarrhœa. From our examination of their action, we think that none of them is in a position to replace morphine clinically.

Dr. George S. Hull, of Pennsylvania, inquired if the author could explain why the acetyl compound exerted such exaggerated effects as compared with the methylmorphine.

Dr. Stockman said that he could not explain this at present, but hoped to in the future, as these investigations are still in progress.

Dr. Murrell spoke of the usefulness of apomorphine as a prompt emetic. The rule laid down in the British Pharmacopœia, to prepare the solution extemporaneously, he regarded as puerile. The solution changes color, but retains its physiological effects for years. He had tried apocodeine, but had not been satisfied with the results and had gone back to apomorphine. In regard to codeine, he regarded it as less satisfactory than morphine and its employment in diabetes as merely due to fashion, and that the profession will eventually go back to morphine.

Dr. Stockman: Codeine is really the more poisonous of the two, although it is usually given in much larger doses than morphine is.

Dr. Brackett believed that codeine was less irritating to the stomach than morphine, and he was pleased with it in cough-mixtures, in cases where morphine could not be given.

Dr. A. L. A. Toboldt, of Philadelphia, read a paper on

CARLSBAD MINERAL WATERS.

In cases of chronic hypochrondriasis he obtained remarkable results from the use of the imported Carlsbad waters. The salts obtained by crystallization were less efficient, but the quell-salz or sprudel-salz powder, given in aërated or plain water, was found to be a good substitute. Mild cases of diabetes mellitus were entirely relieved. One case of obesity lost twenty-six pounds in less than four weeks under the use of the salt. The improvement in this case was permanent.

Dr. George S. Hull, of Chambersburg, Pa., read a paper on

SO-CALLED ANTISEPTIC ACTION OF CALOMEL WHEN GIVEN IN LARGE DOSES.

In cases of dysentery most prompt results in relieving tormina and changing the character of the stools were manifested. It acts as a cholagogue, producing a free flow of bile, sweeping out the contents of the bowel, and as a mercurial it exerts an antiseptic action. In cholera its usefulness in large doses has been advocated by some and denied by others.

In the discussion the relative value of large and small doses of calomel were freely considered by the members of the Section.

In closing the discussion, Dr. Hull said that he was dealing with epidemic dysentery and not with ordinary dysenteric conditions. The first effect of the calomel is to empty the bile-ducts and get a large flow of bile, and relieve the congestion of the liver and intestinal vessels. The second effect is due to the solution of the mercurial in bile, as pointed out by Headland, and this probably acts as an antiseptic in the bowels. The object is not simply to purge the patient, but to obtain a copious bilious discharge from the action on the liver. Where the tongue was most coated he got the best results. He believed that patients are killed by the use of opium and astringents.

SECTION IN ANATOMY.

Wednesday, September 7th—Third Day—Morning Session.

Dr. Joseph N. Dickson, of Pittsburg, Pa., then read a paper entitled

ANATOMICAL CONSIDERATIONS IN REGARD TO THE AMPUTATION AND DISARTICULATION AT THE ANKLE-JOINT, BY A NEW METHOD.

This method was first made public in 1875, and later in 1881. An incision should be made in advance of the

line laid down by Syme, around the sole of the foot from malleolus to malleolus, and also an incision a little above the plane of the articular face of the tibia. The disarticulation was carried out by division of the ligaments of the ankle-joint, and the dissection was begun from above downward and backward, keeping the lateral section in advance of the posterior one. As the knife was carried backward and downward it included the periosteum and bursa between the tendo Achillis and the head of the os calcis. The advantages of this operation are a long plantar flap, shortening of the superior section, division of the malleoli obliquely, and, as stated above, preservation of the bursa between the tendo Achillis and the head of the os calcis. His methods of dressing were also simple. The oblique division of the malleoli allowed a better adaptation of an artificial foot and leg. Of fifty-two cases, three deaths occurred, one or two of which were complicated by other injuries. The average stay in hospital was twenty-one days, and this included patients from four to sixty-five years of age.

Afternoon Session.

Dr. H. C. Boenning, of Philadelphia, Pa., read a paper entitled

destruction of the dissecting-room offal,

in which he spoke of the difficulties of disposing of the waste anatomical material. He enumerated the most usual way of getting rid of this offal by burial, storage, cremation, by alkalies, by mincing it and throwing it in the sewers, by giving it to the buzzards, and by boxing it up and sending it away. He found great objections to all these methods, on account of expense and trouble. He thought he had found the solution of this unpleasant problem by the use of the Gregory furnace, the principles of which were so simple and cost of construction so slight. He found that the small cost of fuel and the small amount of ash left, and the entire absence of foul gas, rendered it an indispensable accession for every school of anatomy. The furnace was lined with asbestos upon the firebrick.

Dr. Boenning further reported a curious

anatomical anomaly.

In the subject, a colored female, aged thirty, was found an *entire absence of the arch of the aorta*. There were two vessels going from the left ventricle, the one up to supply the head, neck, and upper extremities, and the other down to become the thoracic and abdominal aorta. In other respects the subject was normal.

Section in Ophthalmology.

Wednesday, September 7th—Third Day—Morning Session.

Dr. C. F. Horz, of Chicago, Ill., read a paper entitled

restoring the normal position of the free tarsal border in trichiasis.

The essayist began by the introduction of a few anatomical facts bearing upon the subject. He showed that the free edge of the tarsal cartilage in the normal eyelid is placed at an angle of ninety degrees to the surface of the eyeball, and that the eyelashes are inserted at an angle of about ninety degrees to the free border of the cartilage. The angle made by the hairs with the free border may be considerably altered, as in blepharitis ciliaris, without the hairs touching the cornea or surface of the globe. But if the free border of the cartilage is turned inward by shortening of the conjunctival surface of the cartilage from shrinkage caused by inflammation, then it is easy to see how the hairs will sweep over the cornea. This may be remedied either by lengthening the posterior or shortening the anterior surface of the cartilage. It is not necessary, nor does it occur that the curve of the cartilage is changed. Lengthening the posterior surface is impracticable, but it is proposed to show how the position of the free edge can be restored by shortening the anterior suface. An incision is made just below the upper border of the tarsal cartilage, the lid being stretched downward by an assistant, and the skin and muscular tissue dissected off from the cartilage down to the roots of the cilia. Then an incision is made directly back through the cartilage to the conjunctiva, met by another starting from a line about two millimetres above, and the wedge-shaped piece removed. A narrow ribbon of skin being now cut from the edge of the flap, it is replaced, and the sutures carried in through the edge of the flap, then through the upper border of the cartilage, and out through the upper margin of the incision in the lid. The result of this procedure is apparent, the apposition of the edges of the wedge-shaped wound of the cartilage is good without sutures, and the normal appearance of the lid restored. To avoid cutting through the conjunctiva when making the incision through the cartilage the tactile sense of the finger placed on the inner side of the conjunctiva at the free border is sufficient, but a button-hole at this point does no harm, and does not affect the result or the healing.

Dr. B. Pitts, of St. Joseph, Mo., next read a paper on

the best method of operating for entropion.

His paper was an exposition of the advantages of electrolysis not only in removing the troublesome hairs which had assumed faulty position, but also in producing resolution and absorption of the thickened and infiltrated tissues, and in this way, even when relief was only partial, preparing the way for the easier performance of blepharoplastic operations.

Dr. Jones, of Chicago, Ill., spoke of the importance of the subject and the uncertainty of the ultimate result. He had seen several cases where the immediate effect of Dr. Hotz's operation was all that could be desired, but would like to know if the relief was permanent. Some of the cases did not appear so well later on.

Dr. Holcombe, of New York, spoke of a method which he had put into practice, of placing the hairs in position, turned away from the cornea, and holding them in that position by silk surgeon's plaster. He had invariably had excellent results, and renewed the application from time to time as required.

Dr. Frothingham, of Ann Arbor, Mich., thought that Dr. Hotz's operation will give better results than anything we now have. The principal trouble will be in reducing the relaxation of tissue.

Dr. D. A. Thompson, of Indianapolis, Ind., said that while home doctors could not muster as many cataracts as some of our foreign brethren, they had an abundance of this variety of trouble. He thought that no one operation would ever be found suitable for all these cases, and that procedure must be modified to suit circumstances.

Dr. Keyser, of Philadelphia, had had considerable success by removing the entire cartilage.

The President said that Dr. Hotz had apparently dropped the idea of curving out the cartilage, and wished to know the reason. The reply was that the idea of the incurvation of the cartilage had been found to be incorrect, and that therefore there was no need to alter the curve.

Dr. E. Landolt, of Paris, France, read a paper on

operation for strabismus.

He called attention to the marked peculiarities distinguishing this from all other operations on the eye, because it always concerns both eyes. Squint is always binocular. A man with one eye does not squint. Cyclops has no squint. Cataract and other operations may be done without taking into consideration the condition

of the other eye, but not so with strabismus-operations. He dwelt upon the importance of the precautions to be taken for the success of the operation, and the causes of convergence and divergence. A most powerful aid in the correction of squint is the desire for binocular vision. Without binocular vision there is only an apparent cure, a cosmetic effect, because it leaves out the most powerful aid in the cure of strabismus. It is necessary before operation to determine the nature and measure, the degree of the refraction and accommodation, to find how far vision has been lost, and to remedy it if possible. The agents for this purpose are atropia, glasses, cessation from work, and orthoptic exercises. He never operates without satisfying himself that he has got the full effect of non-surgical measures. If the correction is made in the child while young and without these precautions, divergence may occur later. The difficulty of determining beforehand just how much to do to get a certain effect was remarked, and that it was better to do too much than too little. It is easier to diminish than to increase the effect. Dr. Landolt never operates on two homonymous muscles at once. He rather does a tenotomy of one, and an advancement of its antagonist. The remedies for over-effect in operations for convergent squint are stoppage of atropia, removal of stitches from advanced muscle, and use of the other eye. No case should lose its power of convergence or divergence after the operation, as without that power binocular vision would be impossible. If divergence persist, advance the tenotomized muscle. This can easily be done to the tenth or twelfth day.

In divergent squint, on the other hand, the danger is in doing too much. If the divergence is of long standing and the eye amblyopic, then tenotomize with advancement, or do two tenotomies. Do not use atropine, but exercise the eye in the required direction. He often prefers advancement to tenotomy to remedy faulty position. It is more complicated but not more dangerous, and has a greater and more favorable effect than tenotomy. The operation for strabismus is not to be considered as a cure, but only as an adjunct to orthoptic treatment.

Afternoon Session.

Dr. George F. Stevens, of New York, read a paper on

some important problems respecting insufficiency of the ocular muscles.

He said that anomalies of the ocular muscles were of as frequent occurrence as those of refraction and accommodation, while the literature of the subject was very scanty, and what existed would lead one to infer that only one of the muscles was liable to insufficiency—the internus—while the deviations in other directions had been ignored or barely mentioned.

The object of the paper was stated to be to suggest certain problems, rather than to explain apparent contradictions. For instance, a case showed, with a prism over one eye, insufficiency of the externi of 8° at twenty feet, and at one foot insufficiency of the interni of 10°. There was an adducting power of 50°. Now, there could not be an insufficiency of both interni and externi at the same time. Another case, with the prism eliminated from the question, had diplopia, homonymous, of 4° at twenty feet, and crossed, of 5° at two feet. Here seems to be a contradiction of results and a problem to explain.

Dr. Stevens then entered into an explanation of the terms which he used in designating the muscular variations. He uses Orthophoria to express the correct equable balance; Heterophoria to express any departure from it. He divides Heterophoria into Esophoria, a tending of the visual lines inward; Exophoria, a tending outward; and Hyperphoria, a tendency of one image to rise above the other. Latent heterophoria is as common as errors of refraction are, but is often overlooked, and is much more difficult to discover. In case hyperphoria exists, in what way are we to determine in which muscle the fault lies? Again, how shall we determine the absolute amount of anomaly and the best manner of procedure? Dr. Stevens then detailed his own mode of examination, always prescribing prisms of a degree somewhat less than the hyperphoria. He believed it was better to correct too little than too much. He does not believe that prisms are curative or permanently beneficial, but that they are of much use in diagnosis.

Dr. J. F. Fulton, of St. Paul, Minn., in his paper, entitled the

advantages of early operation in strabismus,

spoke of the difficulty of overcoming diplopia or amblyopia where they exist after operation. He agreed with Solberg Wells that suppression of the image results in amblyopia from disuse where the trouble occurs in children, and even in cases where the difficulty is of a later date. He favors operating in children at an early date. If operation is not admissible, then the other eye should be covered, and the squinting eye exercised carefully at short intervals. Amblyopia met with in strabismus is either primary or secondary. If primary and congenital nothing can be done, but he thought many cases were secondary and due to the same cause as the squint. The vision of the defective eye sometimes rapidly deteriorates when the image is suppressed. A case in point was one where V., $= \frac{20}{20}$ in the right eye, and $\frac{20}{30}$ in the left, was raised to normal by a suitable glass. Some time after the fixing eye was lost by accident, when the left eye was found to have only $\frac{20}{80}$. This was raised, after use for some time, to $\frac{20}{30}$. Other cases were quoted, one of two members of the same family, one of whom was operated on, with the result of improving the vision from $\frac{20}{40}$ to $\frac{20}{30}$, while in the other, which was let alone, the degree of strabismus remained stationary, but the amblyopia increased.

Dr. C. H. Abadie, of Paris, France, read a paper on

faulty eye-movements and the means of remedying them,

which was most concise and exhaustive. He reviewed the modes of diagnosis, particularly in relation to the differentiation between those cases that require complete and partial tenotomy, and dwelt on the ability to control the amount of correction by removing more or less of the muscular fibres. It is easy to change a partial tenotomy into a complete one, if it be necessary.

Dr. E. O. Shakespeare, of Philadelphia, Pa., read a paper entitled

on the strength of the superior recti muscles as a cause of asthenopia.

He found many cases of asthenopia not relieved by correction of the refraction, and external and internal recti in which there was want of proper action of the superior or inferior recti. In testing, we may find that the displacement of the image is greater when a prism is placed over one eye than when over the other. If you use a correcting prism you will find one superior rectus stronger than the other. To correct the muscular error, if there is an error of refraction, he discentres the lenses, and if no refractive error is present, then he puts on prisms.

Dr. Landolt gave a demonstration of his method of strabometry, and showed how easily the patient and tapes were placed in position, and the accuracy of the result. The tapes are made by Dubois, rue Monsieur le Prince, Paris.

Dr. H. Power, of London, after stating that it was not so long since the operation was done like dividing a tendon in orthopedy, said that he is not now so certain as formerly of a positive cure. A great deal of care is now taken of the cases before operating, and even with it all

we will have cases that appear to be just as bad after operation as before.

Dr. Shakespeare rose to ask about the successive removal of muscular fibres by Dr. Abadie in small degrees of insufficiency. He wished to ascertain something of the permanency of the relief afforded.

Dr. Landolt, replying in the absence of Dr. Abadie, said that he could not answer that question, as he had never done that operation, and probably never would do it. He always divided the whole tendon. He believed that Dr. Abadie claimed a very good and durable effect.

Dr. G. S. Norton, of New York, asked if Dr. Stevens would tell what was the matter where both external and internal insufficiency appeared to exist, without hyperphoria.

Dr. Stevens replied that that was just one of the problems he had submitted to the Section, and that he did not know.

Dr. J. A. White, of Richmond, Va., spoke of the great value of Dr. Landolt's paper, and added a few remarks on his own results in advancement of the capsule, with which he had obtained as good results in cases of considerable degree as by advancement of the muscle.

Dr. Thompson, of Indianapolis, was afraid that, after all, a large proportion of cases return to their original condition.

The President submitted a question as to the time for operation.

Dr. D. S. Reynolds, of Louisville, Ky., suggests the exercise of the retina with strong lenses, even where considerable amblyopia exists, with the hope of improving vision before operating.

Dr. B. J. Baldwin, of Montgomery, Ala., is satisfied that there are many cases in which amblyopia may be prevented by an early operation. A year or two ago he believed that amblyopia was congenital, but he does so no longer.

Dr. Landolt, in closing, thanked the Section very heartily for their kindness and indulgence, and expressed pleasure at the free discussion which had been drawn out.

Dr. A. G. Heyl, of Philadelphia, Pa., then addressed the Section on

ABNORMALITIES OF THE VISUAL AXIS.

He said that the definition of the visual axis is involved in obscurity, and is as well a matter of extreme importance. He reviewed the terms and definitions at present used, showing their incorrectness, as Gesichtslinie, Blicklinie, and their mechanical and not physiological basis. Collimating axis is better, but it belongs essentially to monocular vision, in which one eye dominates over the other.

His true definition is a line from the macula, directed directly in front when the eye-muscles are in a state of rest or equilibrium. It is a conception low down in consciousness, as is the conception of the median plane.

Through the pull of the tendons on the sclera, the recti muscles keep the macula pointing straight ahead. He then entered into the subject of the origin of the macula—whether from the fœtal cleft, which would call for a rotation of at least ninety degrees, which is said to have been observed. Then he said: "My position, for want of a better, is that the pull of the recti, antagonized by the ciliary muscle, is the factor in the production of the macula." The position of the macula to the outside of the centre, he accounts for by the antagonism of the three third-nerve recti to the one abducens, causing the point of equilibrium to be removed to the outside.

Dr. Ole Bull, of Christiania, Norway, wished to know how Dr. Heyl accounted for the existing of two maculæ in some birds with restricted vision.

Dr. Heyl in closing, in answer to Dr. Bull, stated that he knew that those cases existed, but that he would have to examine the arrangement of the muscles before being ready to explain it. He thought the same process of tension might take place in two different directions.

SECTION IN DERMATOLOGY AND SYPHILOGRAPHY.

Wednesday, September 7th—Third Day.

LUPUS ERYTHEMATOSUS.

Dr. A. Ravogli, of Cincinnati, O., read a paper on the above subject. In his opening remarks the author said that he would always prefer to treat lupus vulgaris than lupus erythematosus, so difficult was it to obtain satisfactory results. Kaposi had regarded the condition as a neoplasm. Hebra first described it as a seborrhœa, but modified the term by adding to it *congestiva*. All authors mention erythema and congestion as important features. Specimens were exhibited, which showed enlargement of the epithelial cells and hypertrophy of the papillæ in the stroma of the corium, and an infiltration of inflammatory cells in the meshes of the tissues, and some cells are seen between the fibres of connective tissue surrounding the hair-follicles. There is an increase in the number of connective-tissue corpuscles. The elastic fibres are swollen and enlarged, and the loculi, formed by the fibres of connective tissue, contain fluid. The blood-vessels are filled with blood. The condition is then one, not of neoplasm, but is an inflammatory process. Each layer of the skin is affected. After a patch of lupus erythematosus has disappeared there is left a thin, white, parchment-like condition of the skin resembling a scar.

There is a true atrophy of the skin, caused by pressure producing obliteration of the glands which first take part in the hypertrophy. The process is then first an hypertrophy of the histological elements, followed by an atrophy.

The cause of the atrophy is found in the blood-vessels being closed and obliterated by pressure. The primary cause consists in an irritation and stimulation of the nerves, which increases the blood-supply and causes a disturbance in the biological activity of the cells.

The author has examined scales from three cases of lupus erythematosus. The epidermic cells were found enormously enlarged, and contained a large number of round bodies which he regarded as micrococci. They formed groups and colonies, and chemical tests appeared to confirm the opinion that they were such.

Sections of the skin were made and showed the existence of the cocci in the papillary layer, most abundant where exudation has taken place, and small colonies in the interior of the fibres and in the capillary blood-vessels.

These bodies answered to the test laid down by Friedländer for micro-organisms, and Dr. Ravogli does not doubt that micro-organisms exist in lupus erythematosus, not only upon the surface, but also within the structure of the skin. He has been unable to make any culture experiments. These organisms he regards as the cause of the disease, and instead of classing it as a neoplasm, thinks it should find its place among the infectious diseases.

The inflammatory symptoms and hypertrophy are explained by the irritation of the micrococci. The function of the sebaceous glands is increased by the irritation, hence the seborrhœa and the formation of the greasy scales. This explains lupus erythematosus discroides; in the form called aggregatus the micrococci still better explain the condition.

As regards treatment, internal remedies are useless, as a rule. The application of emplastrum hydrargyrum has been considered the best treatment. The benefit of this powerful microbe strengthens the theory. When the skin is destroyed with caustics we succeed in destroying the cocci. When the sharp spoon was used to scrape the patches, or they were burned, the disease often returned in the neighborhood of the patch. Dr. Ravogli has obtained complete recovery in three cases of the disease by the use of ichthyol. Diminution in the secretion of the sebaceous glands is soon noticed. The reducing action

of this agent is displayed on the underlying tissues. Ung. diachyl. hebræ goes well with ichthyol (ten per cent.), producing elevation of the epidermis and suppuration. The ichthyol is diminished to three per cent., and only slight scars result. He finishes treatment with ichthyol in collodion. Dr. Ravogli showed microscopic specimens to illustrate the pathological changes and the bodies which he regarded as cocci.

In the discussion, Dr. Knaggs, of England, asked if the reader considered the micrococci as causative, and whether the ichthyol destroyed them and the tissues, too, or acted as an antiseptic.

Dr. Ravogli replied in the affirmative. The ichthyol acted, he thought, by abstracting oxygen, upon which the life of the cocci depended.

Dr. Unna, of Hamburg, regarded as the most important part of the paper that relating to micro-organisms, and he considered it the weak point as well. The cocci must be seen in all parts of the thickness of the skin, and, he believed, in the sweat-glands, too. He thought micro-organisms probably existed in the disease, and would some day be discovered, but could not regard the specimens presented as showing them, and hoped Dr Ravogli would continue his investigations and make cultures. He asked if the sections were made deep enough to show the sweat-glands.

Dr. Ravogli said he had not paid special attention to these glands.

Dr. Unna was glad to hear of the good influence of ichthyol, never having used it alone in this disease, but with the addition of salicylic acid. He had found resorcin beneficial and most useful as a varnish or collodion dressing.

Dr. Thin, of London, said that the refractive particles seen under the microscope might be micro-organisms, and might be other bodies. More characteristic stainings would be necessary and sections carried into the deeper parts, showing the same bodies, before they could be regarded as micro-organisms. Furthermore, cultures and inoculations would be necessary to prove the case. Dr. Thin spoke of several rare cases he had recently seen in England, which, from their peculiar appearance, had been given the name of the cock's-comb disease, as similar cases had not been observed there. The feature of the affection was a raised, bright-red, uneven surface, with abrupt margins. He had examined specimens of the tissue, and had found it identical with that of lupus erythematosus. There was a greater degree of vascularity than usual, the epidermis was raised, and a dense mass of small cells was found between the rete mucosum and strata lucidum. The affection was found very unsatisfactory as regarded treatment. He related one case of lupus erythematosus in which an inexplicable spontaneous cure had taken place while the patient was upon an exclusive milk-diet prescribed for another disease. He believed in a micro-organism, but thought it had not yet been found.

Dr. Klotz was glad to hear Dr. Ravogli say he avoided stronger and caustic remedies. He preferred salicylic acid combined with soap plaster. He thought the discovery of micro-organisms would bring lupus erythematosus into closer relationship with lupus vulgaris, from which it had been too far alienated.

Dr. Zeisler, of Chicago, thought the micro-organism theory a very plausible one; still, it was only a theory. To prove it, it would be necessary to make cultures and inoculations. He did not regard the studies in this direction as entirely new, as Morrison, of Baltimore, had made similar investigations. Lupus erythematosus of the mucous membrane is an extremely rare condition. He had observed it in Vienna, in a case in which the mucous membrane of the mouth was affected. It presented a whitish condition of the membrane, the tissues were hardened, and it proved very obstinate under treatment. Caustic nitrate of silver was alone found to influence the condition. He agreed with Dr. Unna as to the value of resorcin, and that ichthyol had little effect. A 10 per cent. solution of resorcin in collodion had acted well.

Dr. Robinson, the President, spoke especially in regard to the microscopic specimens. He agreed with Thin and Unna that in all probability a micro-organism exists, but he does not think that Dr. Ravogli has pursued proper methods, nor do the specimens show the bodies to be cocci. It is not clear that they are not extraneous matter. We must exercise great care in placing importance upon micro-organisms found upon the surface. He urged Dr. Ravogli to follow up his investigations, and thought something might come of them.

In closing, Dr. Ravogli said that he labored under difficulties in making his demonstrations at this time. He considered the test with caustic potash a convincing one, as it never attacked micro-organisms, but did attack everything else. He was glad to hear the opinions of so many that micro-organisms probably existed. He would not say positively at the present time that they were causative, but would wait until he had been able to make cultures, etc., as suggested.

ERYTHEMATOUS LUPUS OF THE HANDS

was the title of a paper by Dr. Ohmann-Dumesnil, of St. Louis, Mo.

Few cases of erythematous lupus of the hands have been observed or accurately described. Existing upon the hands alone the disease is extremely rare. Treatment is sought usually on account of the appearance.

Dr. Dumesnil related the history of a case in which the lesions appeared upon the hands alone, had existed for a long time, and had been treated by caustic applications without much benefit. He employed concentrated latic acid in the form of a paste, which produced severe pain, and was followed by a slough; pyrogallic acid was also used, but the case passed from observation before a cure was effected. The author has collected forty-five cases. In twelve the disease began in the face, the hands being subsequently affected. The lesions do not extend beyond the nails, and the dorsal surface is the seat of predilection. The patients were usually in good health. Dr. Dumesnil had endeavored to find cocci in the scales and sections of lupus erythematosus, but had not been successful. There is at first an inflammation of the epithelial layer, which subsequently dips down into the hair-follicles, following and affecting the epithelial structures, and only extends to the dermic structures by contact.

CONTRIBUTION TO THE KNOWLEDGE OF IMPETIGO HERPETIFORMIS (HEBRA),

by Dr. Josef Zeisler, of Chicago, Ill., was the next paper read.

Dr. Zeisler first gave a short historical review of the literature of the subject and paid especial attention to the work of Duhring, who, as he thought, went too far in including a disease like impetigo herpetiformis, so sharply characterized by its clinical course, the unmistakable efflorescences, the almost exclusive occurrence in women in connection with the puerperium, the fatal end, etc., with other diseases, under one name, that are so entirely different and mostly of a benign character. He referred to a recent paper of Kaposi, who, describing the disease again in a classical manner, warns against confusion in studying a question which needs so very much to be cleared up. The author then furnished an exhaustive description of a case of this rather rare affection.

In the discussion which followed Dr. Unna related a case which resembled both impetigo herpetiformis and dermatitis herpetiformis, but differed from both and was probably neither. It was similar, as regarded treatment, in that iodine in abundance was the only treatment which gave good results.

It resembled more an impetigo, because the blebs appearing did not from the first contain pus, as is necessary to establish the diagnosis.

SECTION IN GENERAL MEDICINE.

WEDNESDAY, SEPTEMBER 7TH—THIRD DAY—AFTERNOON SESSION.

DR. JOHN A. OUCHTERLONY, M.D., Louisville, Ky., read a paper entitled

THE STUDY OF THE NATURAL HISTORY OF DISEASE.

He was deeply impressed with the importance of the subject in its practical bearing upon the solidity and permanency of medicine as a science. In endeavoring to discuss this he desired not to be understood as belittling in any way that science. It is not only well to admire past achievements but also thoroughly to review the past to ascertain its deficiencies and seek the means most likely to overcome them. The study of the natural history of disease is most conducive to this end.

This subject is difficult on account of the vast scope and the complexity of disease. In looking over the ground we see in every department of pathology unmistakable evidences of the all-pervading presence of laws.

The eagerness of the physician to relieve pain and restore health often causes him to manifest distrust in nature's agency in the cure of disease. Diseases themselves are perfectly natural though not normal conditions of the living body; and the same power which called them into being may also not unreasonably be supposed to be adequate to their removal.

The truth is, nature possesses far greater power in curing disease than is admitted. A knowledge of the natural history of disease is the necessary basis upon which to estimate all medication.

The multiplicity and divergence of scientific opinions result from the neglected study and consequent ignorance of the natural history of disease.

To arrive at a proper knowledge of the natural history of disease, the co-operation of large numbers of medical men throughout the world is necessary, dissecting and attending to the various morbid conditions which affect the human race. These observations must include patients affected with various diseases modified by age, sex, occupation, etc., the duration of the malady, the events marking its course, the mortality, and mode of death. We shall then be in a position to judge with positiveness the value of a drug in shortening disease, preventing complications, or averting a fatal result. There are many obstacles to the execution of such a plan. To some it will appear culpable to withhold the assistance of art, and consign a patient to the exclusive care of nature. Independent of the consideration of the benefits to be derived therefrom, all objections to such experimentations may be fairly met by the following arguments:

First—Since we do not hesitate to subject patients in our public hospitals to treatment with medicines the action of which is imperfectly or not at all known, and consider it legitimate, it can be no less so in similar cases to simply watch the operations of nature.

Second—It must not be overlooked that nature, having inflicted disease, is also in many instances adequate to its cure. This is true of both light and severe diseases—those in their nature grave, such as malignant fevers, tuberculosis, and cancer spontaneously recover.

It is beyond dispute that the worst forms, and apparently hopeless cases of fever, recover unaided by medicine. Tuberculosis has most frequently been recovered from under simply good hygienic surroundings. Hence the steadily increasing favor with which the profession regards the climatic treatment of this formidable enemy of our race.

Third—The strong tendency to recovery in acute affections is often admitted, and is a good reason in many cases for reducing medicinal interference to a minimum, and in many cases amply justifies allowing the disease to pursue the undisturbed and natural course.

Fourth—The character of self-limitation which we now know to characterize many diseases should be a warning to those who entertain exaggerated ideas of the results produced by their treatment, and an encouragement to those desiring to study the natural history of disease.

Fifth—Were it not that the *vis medicatrix naturæ* is no imaginary power, but a living reality, it would be impossible to understand how it is that many quite feeble or absolutely inert medicaments could have attained such a high reputation in the treatment of various and severe affections. To-day "sage" is known to have no medicinal power, yet its history is classical, and it has received the indorsement of the learned as an effective medicinal agent. How many drugs have, like the garden sage, been lauded for imaginary virtues, but after a while have sunk, like it, into well-merited disuse. Yet while in vogue, and medical journals were filled with accounts of their vast powers, it was the *Great Silent Mother* who wrought the cure.

Sixth—The indisputable fact that recoveries take place from similar diseases under quite opposite plans of treatment allows no other inference than that the recoveries are due to nature alone.

Seventh—When one recalls how marvellously patients sometimes get well under the rude and pernicious medication inflicted by quacks, one is forced to conclude that nature is not only adequate to remove the original disease, but also to overcome the artificial disease not infrequently superadded by the *energetic ignorance* of the practitioner.

He was well aware that physicians cannot if they would, and should not if they could, forego all medicinal treatment in the management of all the sick under their charge. But in private practice instances will occur when such a course would be both safe and proper.

The greatest field for observation is in the hospitals. It is well to set aside a certain number of cases and compare the results of medicinal and non-medicinal treatment

Medical students should be taught not to believe in the exclusive power of art in the treatment of diseases, but more prominently the utility of studying their natural history.

DR. CRONYN, of Buffalo, N. Y., discussed the paper. He thought that, as it is the natural history of disease that teaches us, attention to it is best. After all, it often depends upon nature, keeping the patient quiet, and assisting nutrition. The laity think diseases due to a poison varying in degree and intensity according to the severity of the illness.

DR. HEMINGWAY, of Michigan, said: Our work is not as physicists, but as doctors, teachers. I fully agree with all that has been said in the paper. We, as physicians, have made the mistake of following the popular demand "to do something." I think we may sometimes give a little colored water. We may thus not only do the patient but others good, who might otherwise fall into the hands of quacks. In the methods of our studies of disease we should seek to learn the cause, general progress, and termination. We ought to study to aid recovery. We can do our patients no good in any other way.

DR. W. J. SCOTT, of Cleveland, O., was pleased with the paper. He believed we would have a broader foundation by studying the history of the treatment of disease—what has been done, that we may know what ought not to be done. He objected to the too free use of compendiums of medicine instead of thorough and detailed works. He had faith in medicines. He then spoke somewhat out of line with the subject of the paper, upon the increased efficacy of our materia medica and the action of drugs upon specific diseases.

The President, DR. A. B. ARNOLD, said: If we are called to see a patient in an attack of apoplexy, the friends invariably want the patient to do something

when we know that the patient ought to be kept quiet, to allow the clot to form. There is a form of diabetes where an excess of sugar taken into the body will be eliminated by the kidneys in the urine. We know that by taking only as much sugar as can be assimilated the patient will be cured. There is another form of diabetes where the sugar is from the animal tissues, and consequently this is not improved by such treatment. These he gave as examples showing the advantage of a correct knowledge of the natural history of disease in determining treatment.

Dr. Thomas H. Manley, of New York, believed each disease had a special course and tendency to recover. He discussed quite freely the use and abuse of drugs.

Dr. Bell, of Minnesota, gave his idea in regard to the time to use remedies, and spoke of the relation of agents for remedies to the physician.

Dr. S. S. Green, of Buffalo, N. Y., following in the wake of the others, expressed his firm belief in the potency of drugs, but was asked by the President to confine his remarks to the subject of the paper.

Dr. Thomas Hay, of Philadelphia, Pa., stated briefly that he believed in remedies.

Dr. Ouchterlony, closed the discussion by saying that he had been edified by the spontaneous expressions of regard for remedies; there was certainly not a word in his paper in reference to this subject. "I thought when Dr. Scott said so emphatically that he believed in remedies that perhaps he thought I did not." He wished to see an exact science, which could only be realized by the method suggested in the paper.

Dr. Pavy, of London, England, remarked, "I felt that I could not leave without saying I am heartily in accord with the idea that there is a natural history of disease, just as we each have a natural history of ourselves. By studying the natural history of disease we enable our own natural history to have its free play." He believed we needed, as physicians, more knowledge of agencies to cut short the natural history of disease. We also needed medicines to influence the mind as well as the body.

THE DISEASE OF INEBRIETY AND ITS TREATMENT.

Dr. T. D. Crothers, Superintendent of the Walnut Hill Asylum, Hartford, Conn., read a paper with this title. The doctor mentioned the historic fact that inebriety was called a disease long before insanity was thought to be other than spiritual madness. On an old papyrus found in one of the tombs of Egypt, dating far back into antiquity, a clear recognition of inebriety was found. Herodotus wrote, four centuries before the Christian era, that drunkenness was both a disease of the body and mind. Other writers were noted who had urged this same idea, for centuries down to the present. By a strange shifting of events, insanity, which was supposed to be a spiritual affection until a comparatively recent date, is now studied as a physical disorder, while inebriety, which was mentioned as a disease twenty centuries ago, is still invested with the superstition of a spiritual origin.

The doctor said that when inebriety is seen from a scientific point of view, it is found to be controlled by laws which vary according to certain physiological, psychological, and physical forces, of which heredity, environment, culture, nutrition, brain- and nerve-vigor, are most prominent. When accurately recorded histories of many cases of inebriety are studied and compared, certain fixed ranges of causes appear, which follow some regular order of movement. These causes were summarized as follows:

1. Certain conditions of heredity, certain physical and psychical shocks and nerve-injuries, are followed by inebriety in a large proportion of cases.

2. Certain structural changes of the brain and functional perversions, certain disturbances of nutrition, and nerve-irritation precede inebriety in many cases.

3. Certain unstable brain-organizations, regular, retarded, and defective brain-developments, etc., are apparent causes in many cases.

4. Certain diseases seem to have a special predisposition to develop into inebriety without any exciting causes.

These groups were discussed in detail.

In dipsomania and periodical inebriety a condition allied to epilepsy was mentioned. The explosions of the craze for drink were called nerve-storms; the regularity and uniformity of these periods were mentioned.

The uniformity of the symptoms of inebriety were described. Inebriety was affirmed to be increasing, and becoming more concealed every year. The coarser features were giving way to mania and suicide, etc.

The evidence of drink-cycles were described, and the temperance-movements were affirmed to be reactions of the drink-cycles, and governed by laws and forces unknown.

In the treatment, work-house hospitals, conducted on a military basis, were urged, such hospitals to be built from the license fund and made like quarantine stations, where the patients could be controlled and placed in the best condition for recovery.

Different plans of treatment were mentioned in detail, and the profession urged to take up this subject and solve its problems along the line of accurately observed facts.

Dr. E. Cutter, of New York, asked if the doctor was acquainted with the Christian faith-cure.

Dr. Crothers replied that he had heard of it, but was not acquainted with its working.

Dr. Cutter said that he had sent one patient there, who had been cured after ordinary methods of treatment had failed.

Dr. O'Neal, of Gettysburg, thought that we ought to watch carefully, to see if there is any restlessness or tendency to go on a spree. They must be kept in a safe place. In treating the habit itself, he uses a pen made out of oak boards, in which the patient is confined and given nothing but good, nourishing food.

Dr. Fair, of Illinois, thought it the great question of the day. He had tried ordinary remedies, but had found church influences the best. It might be a myth, but it seemed to him that these people are greatly assisted by cultivating an instinct which recognizes a superior being who controls them. He cited the case of a man who went fifteen years without liquor under church influences. This man went away, and was supposed to have been lost; he was found in an isolated building where he had wandered in his delirium, and had become too weak to remove himself; he had now gone ten years without drink.

Dr. George E. Stubbs, of Philadelphia, was reminded, by the paper, of what Dr. O. W. Holmes once remarked: "That in order to treat some diseases, we needed to go back two hundred years." When we know that we are dealing with children from hereditary drunkards, we should properly advise about the bringing up of these children. He had a profound respect for church influences, and the idea of taking your trust in God was always a good thing. But these children must abstain from alcoholic beverages.

Dr. John A. Cutter, of New York, cited several instances where he believed people to be thoroughly cured by religious influence and experience.

Dr. William Waugh, of Philadelphia, said: I believe in these remedies, but for other reasons than that claimed. Inebriate asylums cure only to make the patients worse. On account of the fact that he has been kept idle, is supported by kind friends, and having every attention given him, he becomes indolent and careless, desiring only to be pampered. The patients ought to be made to do physical labor. Too much is now attributed to mental influences; they also need attention given to the physical part of their being.

He had a case where a week before the attack of in-

ebrity there would be an absence of bile in the passages.

Another case was presented to him where there was a red deposit in the urine preceding this attack. Appropriate remedies relieved these cases.

Dr. Cronyn, of Buffalo, N. Y., spoke of the Italian method of treatment, which consists of giving the patient food steeped in wine until he gets a strong dislike to alcoholics. He claimed that this treatment seldom failed.

Dr. Crothers replied that these cases are practically insane. There is no one plan of treatment. Inebriety ought to be considered a disease as much as typhoid fever, and we are as capable of caring for it as any clergyman. He could convert them into the church. They are emotionally diseased, and this conversion is a part of that disease. All these methods, such as faith-cure, moral influences, etc., are good, but such treatment is incomplete.

Dr. Ouchterlony said that some of the greatest drunkards he ever knew had been clergymen, on account of which it seemed improbable that moral influences alone were sufficient for a cure.

Dr. Cisna, of Pennsylvania, read a paper on

TYPHOID FEVER.

The paper was not discussed.

SECTION IN CLIMATOLOGY.

Wednesday, September 7th—Third Day.

Dr. A. Tucker Wise, of Engadine, Switzerland, presented a paper on

THE CLIMATE OF THE SWISS ALPS, WITH PULMONARY CASES TREATED AT AN ALTITUDE OF SIX THOUSAND FEET.

The marked peculiarities of Alpine winter climate may be enumerated as, dryness of the air and freedom from micro-organisms, mechanical irritants, and noxious gases, low temperature, plenty of sunlight, low pressure, and ozoniferous atmosphere. The results of these peculiarities upon pulmonary complaints may be stated thus:

1. By breathing aseptic air free from dust, irritation, or, perhaps, recurrence of infection by microbes in the respiratory tract is greatly lessened.

2. Vaporization of morbid secretions in the lungs takes place, promoted by reduced barometric pressure and dryness.

3. Increased oxidation of blood and tissue from sunlight, cold air, and reduced pressure.

4. Increased quantity of blood circulating in the lungs, the freedom of the circulation being aided by extended chest-movements.

5. Increased activity in the pulmonary lymphatics, and a general improvement in nutrition and glandular secretion; also an exhilarating effect upon the nervous system.

The four principal health-resorts of the Grisons, in Switzerland, are Maloja, Wiesen, Davos, and St. Moritz. The climates of these resorts are stimulating and tonic.

Twenty-three cases were related, showing great improvement during a residence of from one to sixteen months.

A paper by Dr. John D. MacDonald, Inspector-General Royal Navy, on

GROUND AIR IN ITS HYGIENIC RELATIONS,

pointed out the importance of the study of the atmosphere of the soil, but contained no new points of view.

Dr. P. H. Boyce, of Toronto, Canada, Secretary of the Provincial Board of Health, read a paper upon

HOUSE ATMOSPHERES, OR ARTIFICIAL CLIMATES.

The points considered were the constituents of house atmospheres, their temperature and humidity, and air-currents; the effects of house atmospheres on populations, and remedies for existing evils connected with house atmospheres

With reference to the constituents of house atmospheres, the observations of Miquel, Koch, Aitken, and Tyndall upon indoor and outdoor air were quoted. Considerable attention was given to temperature and humidity in connection with house air.

The remedies for the evils mentioned are sunlight in abundance, greater care in the construction of dwellings, foundations, and plumbing appliances, improved municipal sanitation, and the attainment of equable heating and thorough ventilation. In conclusion, it must be recognized, that the fatal effects of the imperfect conditions of human life under which Indians, negroes, and many of the people of limited means exist, demand the earnest consideration of all workers in the field of climatology and demography; and since the occupations, urban residence, and limited means make it impossible for an increasing proportion of our population to enjoy the health-giving influences of rural residence and the stimulating effects of life by the ever-restless ocean, or upon the mountain side, we shall best conceive the duties assigned to us, of making it possible for every willing citizen to so live under his own roof as to maintain a vigor unimpaired for the discharge of the work lying nearest him, and to transmit to the race that is to be a legacy of physical health.

SECTION IN DENTAL AND ORAL SURGERY.

Third Day, Wednesday, September 7th—Morning Session.

Dr. Pradère, of Lyons, France, read a paper on

PHTHISIS CURED BY THE CONTINUOUS APPLICATION OF MEDICINE TO THE PALATE.

Immediately after the paper was read, Dr. James Trueman, of Philadelphia, Pa., moved that it should *not be accepted by the Section*, but should be referred, without discussion, to Section I., in General Medicine; also embodying that the Executive Committee be censured for allowing such a paper to come before the Section. The motion was seconded by Frank Abbott, M.D., of New York, but the Chair ruled that, inasmuch as the Executive Committee had seen fit to admit this paper, it would be out of order to put the motion to the house. Dr. Trueman dissented from the decision of the Chair and renewed his motion. The question being then called, it was voted to refer the paper to Section I.

CLINIC.

A number of gentlemen gave clinics in the treatment of diseased conditions of the oral cavities, and others demonstrated their methods of filling teeth and constructing artificial dentures for patients. These clinics are spoken of as the most successful features in this Section, and it is but just to say that a good deal of credit is due to Dr. C. F. W. Boedecker, of New York, for the result.

Dr. Metnitz, of Vienna, Austria, read a paper on

OSTEOMYELITIS.

The main feature of the paper was the report of two cases from practice.

The history of the first case was as follows: In October, 1886, a lady, aged forty-three, had two teeth extracted. A few days later she suffered with chills, which were followed by slight mental disturbances. The seventh day the patient became unconscious, in which condition she was brought to the hospital. Examination revealed that there was a large swelling over the left cheek, extending to the temporal region; the skin covering this swelling was tense and pale in color; the sclerotic was highly colored (yellow), and the skin showed a yellow tinge; the pupils were without reaction. The odor

of the breath gave evidence of necrosis. The submaxillary glands were very much enlarged, and the neighboring tissues infiltrated. There was unconscious urination and defecation. Death occurred the following day. The post-mortem examination showed the membranes of the brain to be thickened and traversed by numerous vessels. The left hemisphere was covered by a layer of pus, and the right hemisphere showed considerable pus along the track of the vessels as well as several pus-depots. The brain-substance was quite soft. The examination of the oral cavity disclosed that of the two teeth extracted the upper alveolus had almost entirely filled up with healthy granulations, whereas the lower was filled with pus. The mucous membrane in the region of this diseased alveolus was very much discolored and could be easily removed in pieces. The probe discovered nothing but dead bone. All the muscles of the neck which are attached to the left side of the lower jaw were infiltrated with pus. The periosteum was separated from the left side of body and ramus of the jaw. The alveolus of the extracted wisdom-tooth communicated by two good-sized openings with the marrow-cavity, and the marrow itself was discolored and infiltrated with fat. The cause of this extensive destructive action is no doubt to be looked for in the unclean condition of the alveolus after the extraction. Sections of the jaw show that the medullary canal was very much enlarged.

Kocher, Rosenbach, and Busch, in experimenting on animals, have found that it is impossible to produce an acute pus-forming osteomyelitis either through traumatic injury or chemical and mechanical irritation, but that such a condition can readily be brought about by infecting the fresh wound in the bone by any decaying substance.

The second case was one of multiple osteomyelitis. The patient, male, aged seventeen, suffered from an attack of osteomyelitis of the humerus, the ulna, and the lower jaw. According to Billroth, it is not settled whether this condition (multiple osteomyelitis) is due to septic influences acting on various places at the same time, or whether the infection dates from one point.

Death in this case, as in the first, was directly due to acute suppurative meningitis. When we have to deal with a simple inflammation, energetic antiseptic treatment will prove quite sufficient. In severer cases of osteomyelitis Billroth advises that the seat of disease be reached as soon as possible—the pus evacuated, the cavity thoroughly disinfected and dressed with antiseptic dressing. Many cases present no actual depots of pus, or abscesses, but simply an infiltration of the marrow. In such cases Billroth holds it of little value to open into the medullary canal. Neither does he advocate disarticulation or resection, because, in the first place, the exact extent of the disease cannot be foretold, and, secondly, the medullary substance of a patient suffering from osteomyelitis is in such a susceptible condition that a new injury would almost certainly prove fatal.

This paper was read by the essayist in German. No discussion followed.

Dr. Jenison, of Minneapolis, Minn., read a paper on

ART IN DENTISTRY.

The essayist advocated the restoration in gold of all teeth that had been destroyed by caries, thereby improving both their usefulness and beauty.

In constructing artificial dentures more time should be given to the restoration of the features of the patient, and for that purpose single and not section teeth should be used.

Dr. John Allen, of New York, discussed the paper, taking up the main points to be observed in constructing an artificial denture. He closed his remarks by saying that inasmuch as the countenance reveals the thoughts of a person, great care should be exercised in restoring lost features.

AFTERNOON SESSION.

Dr. R. R. Andrews, of Cambridge, Mass., read a paper on

THE ORIGIN OF THE DENTAL FIBRIL, ILLUSTRATED BY AID OF THE STEREOPTICON.

Dr. Andrews described his process of preparing and mounting the specimens for the microscope, which differed in no essential respect from the latest methods employed by others for that purpose.

In speaking of the formation of the fibrils, the essayist says there are two kinds of odontoblasts—those which are square toward the dentine, and others, just by the sides of the first mentioned, which are pear-shaped. From these latter, and not from the first (or square end ones), originate the dental fibril.

The stereopticon views presented by the doctor showed very clearly with what patience, earnestness, and intelligence the essayist worked to establish his view of the question, and the hearty appreciation accorded him by the Section was well merited.

Dr. Frank Abbott, of New York, in opening the discussion, paid a high tribute to the reader of the paper for the hard work done in behalf of his specialty. In order to understand the process by which the dental fibril is produced, it is necessary for us to consider the matter from the third to the fifth month of intra-uterine life, at which period of the existence of the fœtus the papilla of teeth are so far developed that a material change is observed to be taking place. The papilla is a mass of myxomatous tissue, liberally supplied with medullary elements. In some instances at three months, at others as late as the fifth of intra-uterine life, a coalescing of several of the medullary corpuscles into one may be observed upon the periphery of the papilla adjacent to the enamel organ, which at this period may be observed forming a cap upon the papilla. The united medullary corpuscles are known as odontoblasts. The impression has generally prevailed among histologists and embryologists, that the odontoblasts were directly formed into dentine. This theory, through recent researches, has been proven to be incorrect. The odontoblasts, when viewed with a power of 1,200, show a delicate reticulum, which unites the nuclei with the walls of each corpuscle and with each other. This reticulum, as well as the walls of the odontoblasts, are the living matter which remains as the living portion of the dentine. Before the beginning of the deposition of lime salts, the odontoblasts are reconverted into medullary substance. As such they receive the calcareous basis-substance, and thus a certain territory of the papilla becomes dentine. While this process of calcification is going on, another row of odontoblasts makes its appearance, from the sides and ends of which prolongations of the living matter may be seen running into the canaliculi of the dentine already formed. A spindle- or pear-shaped odontoblast gives off one, while those with broad ends give off two, three, and even five, prolongations. If the views advanced in the paper were correct, it would necessarily follow that territories of considerable size would be left in the dentine with no canaliculi whatever; nor is there any provision for furnishing these territories with any living tissue.

Dr. Fletcher, of Cincinnati, O., read a paper on

PROTECTIVE DENTINE, ILLUSTRATED BY STEREOPTICON.

This paper was listened to with great interest by the Section. The slides which were shown on the screen showed the different kinds of protective dentine, and the essayist gave his views of how these different efforts on the part of nature to protect herself are brought about.

Dr. W. X. Suttuth, of Philadelphia, agreed with the essayist in the practical conclusions drawn; he supplemented the reader's remarks by stating that the odontoblasts remain after the development of the dentine, but can be stimulated to produce or perform their function of forming protective dentine.

Dr. W. H. Atkinson, of New York, complimented the gentlemen on producing such well-digested papers.

Dr. J. Howard Mummery, of London, England, exhibited

PHOTO-MICROGRAPHS OF ALL THE STRUCTURES OF THE TOOTH,

and explained the best method of producing them.

SECTION IN GYNECOLOGY.

Wednesday, September 7th—Third Day—Morning Session.

Dr. Ernest W. Cushing, of Boston, read a paper entitled

CANCEROUS DEGENERATION OF THE HYPERPLASTIC GLANDS OF THE CERVIX UTERI.

Ruge and Veit have described a condition of the glands which they considered to be in itself the nature of a cancer—a transition from innocent to malignant formation. This seems to me much less clearly demonstrable than the views which they maintain concerning erosion.

Briefly, they attribute the greater import to a certain filling up of the lumina of the glands with epithelial cells, either columnar or flat. The fascinating theory of Veit and Ruge agrees so thoroughly with Theirsch and Waldeyer and their followers that it has been very widely accepted, and a plate showing the transition is shown in Dr. A. Martin's "Gynecology." I think it possible that greater importance has been attached to this condition of glands than has been warranted.

The question is of practical importance in regard to the microscopical diagnosis of suspicious affection of the cervix, for as it is admitted that the diagnosis cannot be made securely by the unaided eye nor by the touch, and as vaginal hysterectomy is now advocated, and, at any rate, free amputation of the portio vaginalis is indicated in all cases of undoubted cancer, even in an incipient stage, a great responsibility is thrown on the microscopic examination.

In the first place, as Ruge and Veit expressly declare, in their majority of cases the carcinoma did not originate in the new-formed gland, but infiltrated the cervix as a "carcino-sarcoma," an aggregation of small cells lying in masses in alveoli of connective tissue. In such cases there was no evident connection with the epithelium of the surface with the glands.

In four out of twenty-two beginning cancers of the cervix, however, they found appearances of solidification of the glands and filling up with epithelium, which they describe and figure as a transitional stage in the development of the adjacent cancer. With much diffidence I venture to suggest that my studies of the changes in question have led me to different conclusions from these observers.

THE PLATES OF RUGE AND VEIT

are not conclusive on this point.

Even when a whole series of glands lying adjacent to each other show occluded lumina on section, I cannot feel the diagnosis of carcinoma is justified, but only that of adenoma. It may become destructive, but is not carcinomatous until changes occur in the connective tissue between the glands, when the boundaries of the glands are broken through by the growing cells.

Even when the new glands are thus involved manifestly in the carcinomatous growth, it has seemed to me they are invaded from without by the growth of cells in the surrounding tissue. . . . I have found no evidence that after filling up the lumen of a gland the proliferating columnar epithelium changes to the flat variety, and, breaking through the boundary of the gland, invades the surrounding tissue.

Moreover, in attributing so much importance to the fact that they found the lumina of some of the new glands occluded, Ruge and Veit have not noticed the explanation that precisely these solid acini or branches may be the first stage of their existence previous to the formation of the lumen.

Such a mode of growth is seen in the formation of new glands in the walls of a multilocular cystoma of the ovary. These little solid sprouts, lined with columnar epithelium, afterward become hollow and then dilate, forming cysts.

A similar mode of growth is seen in the female breast when rapidly enlarging, preparatory to the secretion of milk.

Where the microscope shows glandular degeneration, the surface bare of epithelium, the tissues heavily infiltrated with small cells, especially if the woman be fifty or over, we should not say that the microscope only shows chronic inflammation, but that

WHILE CANCER IS NOT PROVED, IT IS NOT EXCLUDED,

and should recommend a free removal or destruction of the suspected tissue.

Shall we, then, say that a case is not cancerous which shows no distinct structure of carcinoma on microscopic section, only a glandular hypertrophy, with some of the glands filled with epithelia, and the stroma infiltrated with small cells, the surface denuded of its epithelial cells and irregular?

May we not reconcile the long contest between the two theories, which assign the origin of cancer respectively to the connective tissue and to the epithelial layer of the glands of the involved organ, by supposing that the anatomical arrangement of cells, which clinically and microscopically we call cancer, is only the visible and outward sign of a morbific agent at present hidden from us?

The practical deductions which depend upon our speculative opinions as to the nature of cancer are of the greatest importance.

In the first place, if the disease comes from within, if it is a perverted growth of a part of the tissues, dependent on some original error of development, it is necessarily absurd to try to find, empirically, any medicine which should cure it.

If, however, it is an infection of some kind from without, we are justified in trying empirically, if as yet vainly, for some remedy which may overcome it.

Of more practical importance is the question of the utility of cauterizing the stump or cavity from which a cancer has been removed. There is considerable evidence which shows that surgical interference with a cancer is sometimes followed by a recrudescence of the disease more rapid and violent than the original disorder. If we consider that the operation opens veins and lymphatics which sometimes become infected with the morbific agent, we can better understand why a thorough cautery of the tissues left bare by the removal of a cancer of the cervix should be apparently so useful in lessening the chances of a return of the disease.

Dr. Franklin H. Martin, of Chicago, Ill., read a paper with the title,

A METHOD OF TREATMENT OF FIBROID TUMORS OF THE UTERUS BY STRONGER CURRENTS OF ELECTRICITY BASED UPON EXACT DOSAGE.

The author recognized in the treatment adopted by Dr. Apostoli a rational, harmless, comparatively painless and eminently successful mode of treating fibroid tumors of the uterus by electricity. It is upon these well-tried principles that Dr. Martin is able, after successful practical experiments, to lay down an exact line of dosage, enabling him to obtain all the beneficial effects of electricity without overstepping the limits of tolerance in the most susceptible or sensitive subjects.

The distinctively original feature of the paper was the description by Dr. Martin of his method of exact calcu-

lation of dosage, experiments being cited which showed that a certain local effect may be expected at an active electrode of given surface from a definite strength of current passing for a certain length of time. The demonstrations proved that in order to get the characteristic local effects of electricity on the mucous membrane of the uterus, or to check hemorrhage, upon a surface of one square centimetre, a current of twenty-five milliampères passing for five minutes is necessary. One square centimetre is found to be about the surface represented in length of the uterine sound electrode. Upon this basis of calculation, the uterine canal which would require an Apostoli electrode twenty centimetres in length would require a current, if equal conduction took place from its entire surface, of five hundred milliampères. The author argued that in many cases this strength of current would not be tolerated, and if it were there is no means of being certain that the sound conducts equally from so large a surface or that it comes in actual contact with the mucous membrane of the uterus in its entire extent.

In order to obviate this difficulty Dr. Martin has employed electrodes, concentrating the current to smaller portions of the uterine canal, so constructed that each portion of the canal may be treated at each succeeding operation.

Dr. Martin

RECOGNIZES BUT TWO VARIETIES OF OPERATIONS:

1. Positive inter-uterine galvanism, which corresponds to Apostoli's "galvano-caustique positive."

2. Negative inter-uterine galvanism, which corresponds to Apostoli's "galvano-caustique négative." These operations were fully described, from which procedures Dr. Martin believes we have a safe, painless, accurate, and rational method of treating fibroid tumors of the uterus. By this method all danger to the patient is avoided, such as may be observed in other treatments.

In conclusion, the principal advantages of this method were summarized under six headings: (1) It is entirely free from danger; (2) it is absolutely painless; (3) it invariably checks hemorrhage; (4) it rapidly reduces the size of tumors; (5) it alleviates neuralgic pain; (6) it is a system of treatment of fibroid tumors of the uterus based upon principles which make exact dosage possible.

Dr. Thomas More-Madden, F.R.C.S., of Dublin, Ireland, then read a paper entitled

SOME POINTS IN THE PATHOLOGY AND TREATMENT OF LACERATIONS OF THE CERVIX UTERI.

The pathology and treatment of lacerations of the neck of the uterus have received an amount of attention, in America and elsewhere, which would appear exaggerated were it measured by the comparatively scanty attention as yet accorded it in Great Britain. When he read a paper on Emmet's operation at the closing meeting of the Dublin Obstetrical Society, the very name of that operation, or the circumstances calling for trachelorrhaphy had never been alluded to in the transactions of the premier association of British obstetricians and gynecologists.

In neither English nor American literature had he found sufficient recognition of the frequent complications, pure and immediate, arising from cervical lacerations in obstetric practice; viz., the causation of one of the most troublesome forms of post-partum hemorrhage, and secondly, the occasional occurrence of puerperal septicæmia as the direct result of lacerations of the cervix uteri. So far as he was aware, the advantages of amputation of the mutilated and hypertrophied cervix, in many cases of extensive stellate and bilateral lacerations, over trachelorrhaphy were not generally recognized.

THE RACIAL AND CLIMATIC CONDITIONS

are not so obviously different in London and Dublin from the same in New York and Boston, and any method of treatment found useful on their side of the Atlantic should, *cæteris paribus*, have a like effect in similar cases here. He therefore ventured to submit his clinical experience to the judgment of the Ninth International Medical Congress, and more especially his American brethren therein. It is to them that they who practise in the narrower limits, and perhaps more conservative atmosphere, of the old country are mainly indebted for their present acquaintance with this department of modern gynecology. He was convinced by his clinical experience, which was now tolerably large, that it was a far better and more rational practice, if any operative treatment were really required, to resort to the amputation of the entire extent of the mutilated and diseased cervix by either écraseur or galvano-cautery. H need not say he did not advise this operation indiscriminately; indeed, he thought the majority of cases of cervical laceration needed no operative treatment specially, and such an operation as the removal of the cervix was not to be undertaken without due caution and, above all, real necessity. When thus justified, however, the amputation of the cervix, despite the protestations of some eminent gynecologists, was as unquestionably legitimate as any operation in gynecological surgery. By this procedure, when successful, the surgeon may rapidly and effectually remove every trace of a morbid condition which, if uncured, would probably entail a life of continual uterine discomfort. We may also with certainty prevent the otherwise not improbable possibility of the lacerated and hypertrophied parts becoming the seat of malignant disease at a future period.

Dr. Leopold Meyer, of Copenhagen, Denmark, read a paper on

CONTRIBUTIONS TO THE PATHOLOGY OF INFLAMMATION OF THE LINING MEMBRANE OF THE UTERUS (ENDOMETRITIS CORPORIS CHR.).

1. (*a*) In cases of chronic endometritis, as a rule, we find two varieties of cells, or, rather, of nuclei (as the limits of each single cell are often not distinct) in the inter-glandular tissue. One variety has smaller nuclei; these average as large, or a little larger, than red blood-corpuscles, are stained brightly by hæmatoxylin, carmine, Bismarck-brown, and the substance of the nucleus rarely presents a granular condition.

The second variety has a great resemblance to the so-called decidua-cell.

(*b*) This second variety of cells is not only found in cases where the woman has been pregnant, but is seen in the most developed forms in women whose virginity is unquestionable.

(*c*) This second variety of cells seems, as the first variety, to be derived from the cells normally found in the inter-glandular tissue of the lining membrane of the uterus, the decidua. Cells of the second variety are found in the normal lining membrane during menstruation.

(*d*) Besides these two kinds of cells, we find regular connective-tissue cells and white blood-corpuscles in the inter-glandular tissue.

2. In cases of chronic endometritis the epithelium covering the lining membrane of the uterus can preserve its character of a low columnar epithelium, but it frequently changes character altogether.

Dr. Alfred C. Garrett, of Boston, Mass., read a paper on

TUMORS OF THE BREAST TREATED BY ELECTROLYSIS.

Many, or most of the tumors that so frequently occur in the human breast, we find can be completely cured if treated while young, or new—that is, while in the first stage of existence—by certain mild applications of electricity.

In the first place, to obtain uniform success by this method, we must plan to find these tumors as soon as possible after they form in the breast, while they are in a curable stage in the majority of cases.

However, we already know we cannot assume that

EVERY MORBID LUMP

that grows or appears in the human breast begins from the first a simple or non-malignant tumor, though the most of them seem to do so, judging from the uniformly successful results of these treatments by electricity when applied to the selected, new, or recent tumor.

It is determined that here we must choose the form of electricity and method of application as carefully as we seek to find the curable cases; for we are not to resort to the usual electro-puncture needles, knife, wire, nor any active destructive electrolysis, nor any other means that produce solution of continuity. We are to employ simply surface applications of certain graduated, galvanic, steady currents, through peculiar, large, soft, and moist electrodes, so adjusted close to each side of the tumor as to cause this gently chemical current to completely permeate, and wash through the whole mass from side to side in its deeper parts, mainly in direction toward the axilla, for about half an hour at each *séance*. It is not enough to simply apply the two electrodes to the surface of the breast or in any manner. Moreover, we need to use a milliampère-meter to measure the current that actually passes through the tumor and gland; also a key-board that can enable the operator to pick up and increase the current, cell by cell, to the tolerant and efficient strength, which will be from ten to fifty milliampères. The current required for each individual case cannot be stated in exact terms, as it is found in practice there is a wide difference in the resistance, tolerance, and effect in different persons; yet this point is of great importance.

The result is, that out of 186 tumors treated since 1864, a record of them having been kept and looked after, 157 disappeared and have remained well. Several others did not quite obliterate, however, but left a small nodule, the size of a chestnut, which in every case disappeared or remained benign.

AFTERNOON SESSION.

DR. W. H. WEEKS, of Portland, Me., read a paper on

MYOMA IN PREGNANCY.

He considered the question of operation in these cases to be still under discussion. He introduced the paper by the relation of a case—a young lady, pregnant, having a large uterine fibroid which nearly filled the uterine cavity. He was in favor of allowing the pregnancy to go to term, and such was the opinion of a Boston gynecologist to whom he sent her for counsel. A New York gynecologist, however, advised immediate delivery by the induction of premature delivery. The method by which he would do this was to inject hot water and deliver under ether *per vias naturales*. If allowed to go to term laparotomy would be necessary. Two Boston gynecologists agreed with him, and the author was obliged to surrender. He carried out the instructions of his colleagues to the letter. The patient died in less than an hour after delivery. She seems to have died of hemorrhage and shock. When, as in this case, pregnancy is complicated by a large interstitial uterine fibroid, occupying and wellnigh filling the cavity of the pelvis, is it better to induce abortion or premature labor or to allow gestation to go on to full term, and then deliver by abdominal section?

GUIDED BY THE LIGHT OF ABDOMINAL SURGERY,

I shall maintain that in the vast majority of cases, as stated in the above question, it is better to allow pregnancy to go to term and then, if it is found that delivery is impossible *per vias naturales*, to resort to abdominal section without waiting till the patient's strength is exhausted by protracted labor. The operation best suited to such a case is Cæsarean section, Sänger's method, and then the removal of the ovaries, and, if possible, the Fallopian tubes. Would it not have been better in this case to have allowed the patient to go on to natural labor, and then performed laparotomy before she was broken down?

The author had sent out letters of inquiry to prominent gynecologists of this country and abroad. Nine out of thirteen physicians were in favor of the induction of premature labor. This proportion he hoped would be reversed.

DR. GRAILY HEWITT, of London, opened the discussion and commended the paper very highly.

IT IS A THANKLESS DUTY

to bring an unfortunate case before the Congress, and Dr. Weeks should have our admiration for doing so. He thinks it is generally admitted that rapid evacuation of the uterine cavity in labor is a mistake. The operation in this case seems to have been done rather rapidly. Whether this had anything to do with the hemorrhage and shock he did not know.

DR. TRENHOLME, of Montreal, had had three cases of labor complicated with fibroids, which he related in brief. In one of these premature labor was brought on by a sessile tumor in the base of the uterus. The temptation to remove the tumor was great, and he did it, but the patient died. In his second case he found a small fibroid, which he left alone. The patient did well for some time, but had a return of the trouble. He believed evacuation of the uterine contents should take place slowly.

DR. LAWRENCE, of Bristol, England, discussed the question,

SHOULD A WOMAN SUFFERING FROM FIBROID TUMOR BE ALLOWED TO MARRY?

This is a question frequently presented to the physician and gynecologist. If the patient is not suffering from symptomatic troubles you may tell her that she will probably never be pregnant, but if pregnant she will probably have hemorrhage and may die of it. With this understanding, if she persists let her marry. The doctor reported eight cases in brief. In one of these, after a large number of pregnancies, the tumor disappeared entirely.

DR. S. C. GORDON, of Maine, said that the case of Dr. Weeks was originally his own, and he felt like saying something. He agreed with Dr. Weeks that no abortion should be induced in this case. The position of the uterus in this particular case forbade the operation in his mind. The position of the tumor influences very largely our procedure. He reported a case. In a second case which he cited he advised the induction of abortion, because the tumor involved the anterior wall of the uterus low down to the os.

DR. ALEXANDER DUNLAP, of Springfield, O., read a paper on

THE EARLY HISTORY OF OVARIOTOMY IN AMERICA.

This was a *résumé* of the trials and oppositions which the early American ovariotomists met with in prosecuting their work. The author's own work, which is well known to have been of great importance, though little of it has been published, was described minutely.

Early in 1843, with a very limited knowledge of medicine and surgery, he came in contact with a very peculiar case of ovarian dropsy which he had been led to consider as incurable. This he tapped several times, with the usual results. [He then went into the history of his first ovariotomy with all the enthusiasm of forty years ago, and by the way he described it one would have thought that he was with the young surgeon at the patient's house doing the operation.] After much delay the patient succeeded in forcing him to perform the operation, much against his will. He invited ten of his medical friends to witness the operation. They declined, saying that they could see enough people die without seeing

them killed. One of them presented himself at the time. He was an old retired army surgeon who was addicted to drinking. With this assistant and four students he operated, first giving the patient a teaspoonful of laudanum, after which he went to work (applause). The operation was carefully described. The patient was placed in bed after the operation, with no especial shock, having watched every movement made with care and interest. She did well for four days, when she had a severe diarrhœa which was brought under control. She progressed favorably for a time, when she was taken with an excessive excretion of urine and died on the twentieth day after the operation, evidently from excessive drainage from the kidneys. There was no septicæmia. He was convinced that she did not die from the operation but from the tappings, which had deranged the system and were probably the cause of the kidneys acting as they did. He had no doubt that had he operated when she wanted him, she would have been alive to-day. His reports of this case were

REFUSED PUBLICATION

by the Cincinnati journals.

Dr. Kimball, of Lowell, Mass., was then called up by the President to give his experience in early ovariotomy in the East. His story was quite similar to that of Dr. Dunlap, and his opposition as great. This opposition, he must say, came mostly from the New England metropolis, Boston. Being asked for his first case, he said his first case was one in which he did not operate. He then reported the first case in which he did operate about thirty-five or forty years ago. He invited ten physicians. During the operation he met with considerable difficulty in the form of nine cysts, and when he looked about for his assistants they had all left but one.

Dr. Bozeman, of New York, reviewed the revival of the history of ovariotomy after its abandonment by McDowell, of Kentucky, and its condemnation by the profession. Dr. Miller was the first to use chloroform as an anæsthetic in ovariotomy in America. It was in Terre Haute, Ind., and he, Dr. Bozeman, gave the chloroform. He credited Dr. Dunlap very much for his work, and especially for what he had done in recognition of the importance of adhesions.

Professor A. Cordes, of Geneva, Switzerland, read a paper on the

MEDICAL TOPICAL TREATMENT OF UTERINE CANCER.

The paper was divided into a general consideration of the subject: Medical and surgical treatment; the opinions and treatment of Hippocrates and Celsius; the obscurity of the primary symptoms; the impossibility of hysterectomy in certain cases; adherence and extension to other organs; statistics; topical applications; the treatment of advanced periods of cancer by turpentine, the properties of this remedy, its application and preparation by M. Betrix, assistant to the clinique. The paper closed with a series of conclusions to which the author had arrived.

A paper was read by Dr. A. Lapthorn Smith, F.R.C.S., of Montreal, on

A NEW THEORY AND TREATMENT OF DISPLACEMENTS OF THE UTERUS BY ELECTRICITY,

and one by M. le Docteur Apostoli, of Paris, entitled

SOME NEW APPLICATIONS OF THE INDUCED OR FARADIC CURRENT TO GYNECOLOGY.

SECTION IN DISEASES OF CHILDREN.

Wednesday, September 7th—Third Day—Morning Session.

Dr. Cyrus Edson, of New York, read a paper on

THE MILK-SUPPLY OF CITIES,

calling attention to the great importance of improving and maintaining the standard of milk-supply by banishing adulterated and infected milk. He advocated the examination by veterinary inspectors, from time to time, of every herd of cattle in the State, in order to secure the destruction of all animals suffering from tuberculosis, and the quarantine of those liable to cause contagious disease.

Professor Albert Leeds, of the Stevens Institute, Hoboken, N. J., stated that the work done by inspectors in preventing the dilution of milk is important from a commercial rather than a sanitary point of view, as water is in itself a harmless adulterant. The best work is done when official inspection is extended so as to include the pasture, the stall, and the dairy. Skilled and scientific effort in this direction would prevent the spread of infectious diseases from cattle to man.

A French paper was then read by Dr. Paul Redard, of Paris, on

THE TREATMENT OF ERECTILE TUMORS BY ELECTROLYSIS.

The writer described in detail the method proposed by Ciniselli de Crémorne, which, with some modifications, he had found satisfactory in a large number of cases in dispensary practice. The operation is moderately painful, and the effect rapid, with no suppuration or scars.

Dr. de Valcourt, of Paris, then read a paper on

THE TREATMENT OF TUBERCULOSIS BY SEA-BATHING.

Afternoon Session.

Dr. Isaac N. Love, of St. Louis, Mo., opened the session by reading a paper on

INFANTILE MARASMUS.

He reviewed a class of cases distinct from those caused by tuberculosis, syphilis, and intestinal catarrh. In an advanced stage they present a picture the principal features of which are wasted muscles, prominent bones, a loose and dry skin, and face withered, wrinkled, and worn. A careful study of a large number of such cases had suggested to him the following conclusions:

1. Infantile marasmus is dependent primarily on torpidity and inactivity of the glandular system, and is aggravated by unsuitable, over-abundant, or insufficient food and insanitary surroundings.

2. It is of the first importance, in treatment, to arouse secretion and excretion, the best remedy being calomel in one-twentieth of a grain doses, with the free administration of water; both of these agents exciting glandular action, stimulating the secretion of the digestive juices, and promoting diuresis and intestinal secretion.

3. "In the matter of diet, the mother's milk is the best, and some other mother's milk the next best."

4. In extreme cases, administer soluble foods in the form of baths, and practise gentle friction and massage, with an occasional bath in water containing a diffusible stimulant.

A paper was then read from Dr. William Henry Day, of London, entitled

SOME OBSERVATIONS ON HEADACHES IN CHILDREN, AND THEIR RELATION TO MENTAL TRAINING.

The writer considered the characteristics of nervous frontal and neuralgic headache, and the condition known as irritable brain. One form or the other is the first and most persistent symptom of the breaking down which follows the mental over-pressure which now prevails in education and in the competitive examinations for entrance in every profession and in every branch of the public service. The irritable brain is not infrequently accompanied by myopia, hypermetropia, and astigmatism.

Dr. William S. Dennett, of New York, recognized the type of headache to which Dr. Day had referred as associated with refractive troubles, as well as the occipito-cervical discomfort associated with muscular insufficiency. It would be well if all cases of incipient myopia were attended with a forewarning headache.

Dr. William D. Booker, of Johns Hopkins University, then read a paper, entitled

A STUDY OF SOME OF THE BACTERIA FOUND IN THE DEJECTA OF INFANTS AFFECTED WITH SUMMER DIARRHŒA.

Twelve different varieties of bacteria had been isolated. Eleven were bacilli and one belonged to the cocci. Two of the bacilli only liquefy gelatine. Their action on milk is as follows: Some coagulated casein with acid reaction and evolution of gas, one variety caused coagulation with alkaline reaction, one gave the milk a peptonized appearance, other varieties caused no perceptible change.

In guinea-pigs, young kittens, and white rats and mice the post-mortem results were fully detailed in the paper, and an interesting discussion followed.

SECTION IN MILITARY AND NAVAL SURGERY IN MEDICINE.

Wednesday, September 7th—Third Day—Morning Session.

The first paper of the day, upon

THE PROPER TREATMENT OF PENETRATING WOUNDS OF THE JOINTS.

was read by the author, Professor Frederic Hyde, of the University of Syracuse, N. Y.

After a critical review of the history of the subject, of the methods advocated by various civil and military surgeons for the treatment of these wounds, and the textural changes resulting therefrom, the author stated that the result of the wound, whether incised, lacerated, contused, or punctured, depends upon the intensity of the inflammation and the destruction of tissue, and presented his views as to the treatment. These may be summarized into: The arrest of hemorrhage; treatment of shock; the removal of foreign bodies from the wound, which should be enlarged, if necessary. In all cases of suppuration a direct opening should be made for its evacuation. After any form of injury an effort should be made to save the limb; perfect immobility should be secured by plaster-of-Paris or other fixative dressing; finally, pain should be alleviated, and the general condition be improved by stimulants, good food, and the like, according to indications. The treatment of the injury throughout should be antiseptic. The speaker contrasted the earlier treatment of joint-wounds, which forbade the opening of a suppurating synovial sac, with the treatment of to-day, and characterized the former as the spoliative and the latter as the saving treatment. Amputation should only be resorted to as a *dernier ressort*.

The next paper, upon the same subject, by Dr. George L. Porter, of Bridgeport, Conn., was then read. It had especial reference to the injuries of the larger joints, particularly that of the knee. The treatment should be adapted to each individual injury; aseptic precautions, complete rest, the ice-pack, and expectant treatment generally the author thought to be applicable to most cases.

Dr. Eli A. Wood, of Pittsburg, Pa., read a short paper on this important subject, which in the main agreed with that of Dr. Hyde.

Dr. Marston, of England, favored amputation.

Dr. Janes, of Waterbury, Vt., stated that his experience had been an unfortunate one, all his cases having died.

Dr. Gregory, of St. Louis, inveighed against resorting to amputation, and favored the opening of the wound under aseptic precautions and removal of foreign bodies, and careful supporting treatment.

Dr. G. T. Langridge, of England, spoke of his large experience in wounds of the knee-joint produced by machinery; under aseptic treatment a very large proportion of cases recovered completely.

Dr. L. von Farkus, of Budapesth, stated that during the late Servo-Bulgarian War there were observed nineteen cases of gun-shot penetrating wounds of the knee-joint, all of which were, with one exception, treated by fixation by the plaster-of-Paris bandage, after free opening under antiseptic precautions and drainage; fever was absent in all cases, and all recovered, including the exception mentioned, which was a case of injury so serious as to require amputation.

Afternoon Session.

The paper of Dr. W. S. Tremaine, U. S. A., entitled

IS LAPAROTOMY FOR GUN-SHOT WOUNDS OF THE INTESTINES FEASIBLE IN MILITARY PRACTICE AND ITS TECHNIQUE?

and another upon

THE TREATMENT OF PENETRATING WOUNDS OF THE ABDOMEN, WITH WOUND OF THE INTESTINES,

by Dr. Francis Patrick Staples, of the British Army, were read by title.

An abstract of a paper upon

THE PROPER TREATMENT OF PENETRATING WOUNDS OF THE ABDOMEN,

by Dr. S. T. Armstrong, U. S. A., of Memphis, Tenn., was, owing to the absence of the author, read by Dr. Smith, of the army. The main points brought out by the writer were, that the treatment depends upon the part injured; rest, sedatives, expectant treatment, with laparotomy as a last resort.

The next paper, also upon this important subject, entitled

ON NON-FATAL PENETRATING GUN-SHOT WOUNDS OF THE ABDOMEN TREATED WITHOUT LAPAROTOMY,

by Henry Janes, M.D., of Waterbury, Vt., was read. The author began by saying that the tendency at present is to too much operating upon the abdominal cavity. He had tabulated the cases observed by himself during the late war, of penetrating gun-shot wounds of the abdomen, covering twenty-seven cases, eighteen of which were complicated by lesions of the abdominal viscera, and other cases of injury to pelvic and abdominal organs. In none of these cases were operations performed, except for the purpose of removing fragments of bone, the missiles, or other foreign bodies.

SECTION IN LARYNGOLOGY.

Wednesday, September 7th—Third Day—Morning Session.

Dr. H. H. Curtis, of New York, being absent, his paper on

SURGERY OF THE NASAL SEPTUM AND TURBINATED BODIES

was read for him. He classified various deformities of the septum so as to more accurately describe the different operations. Operations on the turbinated tissues were disposed of in systematic manner, and attention was given to catarrhal conditions of ethmoidal cells.

Dr. F. Massei, of Naples, Italy, sent a paper on

PRIMARY ERYSIPELAS OF THE LARYNX.

Dr. Massei being absent, his paper was read for him. It opened by quoting a list of authors who admitted that there was a primary erysipelas of the larynx. It is fortunately a very rare disease, and no good clinical history is given showing the laryngeal appearance. The disease

is usually secondary to erysipelas elsewhere on the body; where primary it is found in hospitals where the air is bad, and where the patient's bed is near that of another who has an attack of erysipelas. The disease may begin in the throat and attack the skin later. In 1885 his attention was called to cases in private families where there was primary erysipelas of the larynx. The cases had not been exposed, to his knowledge, to infection from other cases of erysipelas. There was no manifestation of the disease elsewhere on the body. Noticed one form where the local symptoms were most prominent, and another where there was an early collapse. It may extend to the lungs without any external appearance of the disease.

Early symptoms are, difficulty of swallowing and talking, change of voice, with pain; fever is high, and pulse rapid. Epiglottis swollen; mucous membrane of larynx intensely congested and reddened, also much swollen. Narrowing of glottis even to suffocation may occur as symptoms increase in severity, and we find aphonia and dyspnœa, caused by swellings and œdema over arytenoid cartilages and ary-epiglottic folds. The swelling has a way of migrating from one part to another, may sink down on one side and the other become rapidly tumefied. The swelling of a part is preceded by intense congestion. Frequently there is an eruption of blisters or bullæ. These burst and form crusts with mucus and blood. Fever is more or less relapsing; temperature varies from 40° to 38° C., but is not periodical in its changes. Lymphatics are very sensitive, and neighboring glands are swollen and inflamed. After several relapses of temperature, we may have resolution and recovery, or death from asphyxia if tracheotomy is not resorted to, or collapse from extension to the lungs. More apt to extend to the lungs in the aged. In treatment, use ice or coil to the larynx, also counter-irritants; use bichloride, one to two thousand, as a spray. If patient cannot swallow food through a tube when œdema or bullæ interfere seriously with breathing, then scarify, and resort to tracheotomy if necessary. In migrating from one part to another, it may be rapidly fatal, so as to give no time for action. Treat the disease by symptoms.

Dr. Stockton, of Chicago, saw a case of a powerful and healthy man, who came to Chicago for nasal trouble. Contracted what he thought was severe cold. Had symptoms rapidly increasing in severity; pulse, 140; temperature, 103½°, preceded by severe rigors. Great difficulty in breathing, with aphonia. Epiglottis thick and red, so also arytenoid and folds between, and thickly covered with small blebs. More or less œdema over the arytenoids, with numerous blisters. Ventricular bands covered the true vocal cords, and almost completely closed the glottis. Tried intubation, which worked perfectly to relieve dyspnœa; but the redness of the erysipelas extended over the pharynx to post-nasal space and through the nose, then over face and eyes to the forehead. Recovery.

Dr. Benham, of Pittsburg, Pa., thought it more common than usually supposed, and there was no disease more distressing or likely to tax the physician's resources more. He has never seen it primary. Instant relief from scarification. Cannot understand the sudden recovery that sometimes occurs.

The President (Dr. Daly) thinks that mustard and external irritants are beneficial, if used early. He thinks that intubation would favor gangrene.

TWENTY YEARS OF LARYNGOLOGICAL WORK IN THE CITY OF MEXICO,

was the title of a paper sent by F. Semeleder, M.D., of Mexico. It treated chiefly of the difficulty of getting books and instruments early in his career, and described how laryngology was unknown there. He gave a list of prevalent troubles, and the various operations he had performed.

PRESENT STATUS OF THE GALVANO-CAUTERY IN THE TREATMENT OF THE DISEASES OF THE UPPER AIR-PASSAGES, ILLUSTRATED BY INSTRUMENTS AND THE DESCRIPTION OF CASES,

was the title of a paper by F. B. Eaton, M.D., Portland, Ore.

The author being absent, the paper was read and the instruments exhibited.

Inventive faculties stimulated continually to devise more radical methods of treating nasal catarrh. Must avoid over-medication, over-treatment. Considers specialists a necessary evil. There will be a reaction and less operative interference result. Defends galvano-cautery against attacks of being cumbersome and expensive. It is only relatively so. It is never disappointing in its results, but surpasses one's expectations. Not as much disliked by patients as acids, and easier to regulate the effect. Patients fear it less than knives, saws, and snares. No pain when twenty per cent. of cocaine is used. Operation is clean, with no hemorrhage; can remove small exostoses and cartilaginous masses, but not where they are large. A saw is better here. Puncturing them may cause enlargement and fatty degeneration. Treat hypertrophies by puncture and incision with cautery. Leave puncture and move the point freely in the mass, so as to cause contraction without destroying the external tissues. Battery and various electrodes exhibited. He has in operating used rigoline, after Dr. Jarvis' method.

Dr. R. H. Thomas agreed with Dr. Eaton's conclusions as to the general applicability of galvano-cautery, but did not consider it as successful for large hypertrophies as the cold snare. He considered twenty per cent. of cocaine as far from safe for indiscriminate use. He has seen too many unpleasant effects from even weaker solutions. Never needs over ten per cent. as the highest.

SECTION IN OBSTETRICS.

Wednesday, September 7th—Third Day—Morning Session.

DISCUSSION ON CÆSAREAN SECTION.

Professor Alexander Simpson, of Edinburgh, Scotland, was in accord with the ideas expressed in Dr. Lusk's paper, though he did not think the time yet come when craniotomy could be entirely laid aside; its performance, however, should be restricted. In Edinburgh pelvic deformity was rare and craniotomy was rarely required.

The cases requiring abdominal section could be divided into two groups—first, those where the prognosis was rendered grave by pre-existing inflammatory conditions or sepsis, and, second, those favorable cases where we could choose the moment and place of operation, when we should nearly always succeed. At present he would be bold who would perform Cæsarean section by other than the Sänger method. Where the uterus was diseased and its removal would give the patient a chance, he would employ Porro's method.

Professor August Martin, of Berlin, Germany, considers the Sänger modification very important, and one which has rendered the operation safe. Since the adoption of this modification the section had been done in some cases where he thought version could have been safely performed. In moderate degrees of pelvic contraction we should ascertain whether delivery could not be effected in other ways, as by version, before performing the section. Had done the Cæsarean in pregnancy complicated with cervical myomata. Sänger had operated in similar cases. Where carcinomata of the organs in the pelvis endangered life we should endeavor to deliver child and remove growth at the same time. When the uterus was infected by septic material it should be removed. In a rachitic, kyphotic woman, with heart and lung disease, the symptoms were so grave that he did

not think the woman would stand normal parturition or the puerperal state; accordingly he had done abdominal section, saving both child and mother, who finally died from her lung trouble. Much depended upon our knowledge of the technique; if we succeeded in doing the operation perfectly, either the Sänger or Porro operation was justified. The statistics of the Porro operation were rendered less favorable by Italian operations done on unfavorable subjects who were septic and in whom the operation was too long delayed. The Cæsarean section always gives us hope of perfect recovery, while the Porro operation prevents future maternity.

Abdominal section is indicated when it seems impossible to bring a living child through the pelvis (take care not to operate too soon); when neoplasmata narrow the canal or endanger the progress of parturition; and when diseases are present in which the life of mother and child would be endangered by the process of parturition or the puerperium.

The Cæsarean section should be done when we have reason to believe that the patient can endure another pregnancy; the Porro operation, or total extirpation, when there is no hope of future maternity or where the disease, from its nature or seat, is probably fatal.

Dr. Joseph Taber Johnson, of Washington, D.C., reiterated the opinions expressed by Drs. Lusk and Wathens. He believed that by delay and the attempt to perform other operations many lives were lost. He advocated the Porro operation when the uterus was septic or bruised. The wonderful results of foreign operators were due to their exceptional opportunities and skill, the operations being done by a few men, while here the operators were scattered, and many operations had been done in the backwoods. He thought that soon American surgery would reap as brilliant a reward as that abroad.

Dr. Balls-Headley, of Melbourne, Australia, advocated the Cæsarean section when the child could not be born alive through the natural passages. There were also certain conditions, as carcinoma of the cervix, where other operative interference would allow the child to be born, but in these cases his experience taught him that the Cæsarean section offered a very much better prognosis. The operation was an easy one. In slight pelvic contraction the section gave good results. We should operate early, or, if the parts were bruised, substitute the Porro operation.

Dr. Doléris, of Paris, France, accorded with the views of Lusk and Martin. He believed in the use of the elastic ligature.

Dr. W. W. Jaggard, of Chicago, Ill., said, with reference to the *relative indication* for Cæsarean section, that in cases where the child could pass *per vias naturales*, when diminished in volume, with safety to the mother, as, for example, in pelvic contractions of from 6 to 8 ctm. in the true conjugate, four considerations should receive attention:

1. Craniotomy does not require a higher degree of operative skill than every qualified obstetrician ought to possess, when proper instruments are employed, *e.g.*, Braun's curved trepan and cranioclast.

2. The mortality of craniotomy, when performed in time, and before exhaustion and infection of the woman, with adequate skill and antiseptic precaution, is, as remarked by Barnes, practically nil.

3. The consent of the woman, obtained without direct or indirect coercion, an essential condition of the relative indication, is seldom gained, if the facts be presented to her.

4. That there is much sentimentalism with reference to the value of the life of the child in utero, as compared with the value of the life of the mother. This interest in the child is purely impersonal and scientific. The delight in saving the child's life is frequently that arising from the success of a difficult scientific experiment.

Dr. William T. Lusk, of New York, said that the points made by Dr. Jaggard were opposed to his recent investigation. With skill we could remove a living child where the contraction was only 7 to 10 ctm. Craniotomy was a dangerous operation, and, under three inches, required much skill and good instruments. He believed the Cæsarean section not more dangerous than the extraction of the child after craniotomy.

In his recent case the operation was done in the open ward, with the same preparations as for ordinary laparotomy. The children, according to his researches, did not die, as general opinion would have it. The Cæsarean section was easy to do. He thought there was danger, in the employment of the elastic ligature, from paralysis and inertia, caused by the compression. We did not want to encourage trying craniotomy and then Cæsarean section, but should make the lattter the operation of election. Most of our cases had been done under circumstances which had rendered death inevitable.

Afternoon Session.

Dr. J. A. Doléris, of Paris, France, presented a paper on the

TREATMENT AND SURGICAL RESTORATION OF THE CERVIX DURING PREGNANCY.

He first described a case where at a previous pregnancy the cervix had been very extensively lacerated. The patient was again several months pregnant, and suffered from a profuse, fetid, probably gonorrhœal discharge. There was severe vaginal pain, and the cicatrix of the cervical laceration was very painful when touched. Preliminary treatment did not relieve the patient and the cervix was sewed, four sutures being placed on either side, and the vagina filled with iodoform gauze. The result was excellent, with no interference with the pregnancy.

This was only one of several similar cases where he had operated successfully.

A severe laceration accompanied by profuse and fetid discharge was very distressing, and might lead to abortion or puerperal fever.

He thought the danger of producing abortion by the operation was exaggerated, and that in the class of cases mentioned it produced good results.

Dr. Opie, of Baltimore, recalled a single case where a severe bilateral laceration of the cervix had been operated upon; the woman proved to be pregnant, and aborted on the sixth day. There was objection to any operation about these parts during pregnancy, especially early pregnancy. Cervical operations were not without their special dangers at this time, and should be but rarely done.

Professor Leischman, of England, said that preconceived opinions often stood in the way of new truths. His preconceived opinion was that operations about the cervix were likely to produce abortion, especially when not done by the most skilled hands. Any operation during pregnancy, and this in particular, should be done only in rare and strictly defined cases.

Dr. Doléris responded that he had not advised the operation except in the well-defined cases he had mentioned, and in which he thought it would rather tend to prevent abortion.

Dr. Joseph Kücher, of New York City, read an elaborate paper

ON THE RELATION OF THE ATMOSPHERE TO PUERPERAL FEVER.

He spoke of the importance of pure air in the lying-in room, and put the question: What influence has an impure air on puerperal fever? A *résumé* of the literature and statistics of the subject shows that the malaise of dissecting-rooms is more due to impure air than to absorption of septic material, and that true sepsis occurs only by inoculation through an open wound.

Overcrowding does not necessarily cause puerperal fever when septic infection is prevented. Pure air undoubtedly allows of more rapid convalescence; bad air depresses and allows the more easy access of septic infection; sepsis does not occur from bad air alone, but only from direct contact with septic matter.

Dr. Thomas More-Madden, F.R.C.S. Ed., of Dublin, Ireland, presented a paper

ON THE PREVENTION AND TREATMENT OF PUERPERAL SEPTICÆMIA,

which was read by the Secretary.

The author considers all forms of septic fever consequent on parturition, and occurring within the puerperal period, as various manifestations of a specific puerperal fever. Puerperal sepsis may originate in three ways, viz., from inoculation with the micrococci of clinically allied diseases, such as erysipelas or scarlatina; from infection by the pathognomonic, chain-like micro-organisms evolved by other puerperal-fever patients; or the disease may arise from auto-infection with self-generated septic matter. Although absolute immunity from puerperal fever must be considered hopeless, its prevalence may be much diminished, and its virulence minimized, by the rigid observance of certain precautionary antiseptic and hygienic measures.

For prophylaxis the author strongly recommends the administration, during the latter months of pregnancy, of the chlorates of iron, potash, and quinine. Strict attention to the patient's local and general hygienic and aseptic condition is insisted upon. The author uses a carbolized intra-uterine douche daily throughout the puerperium, together with large doses of ergot for the same time.

In the treatment of puerperal fever he relies primarily on the maintenance of the patient's strength by suitable nourishment and stimulants; secondly, on the daily washing out of the uterine cavity with hot water, plain or medicated; thirdly, on full doses of quinine and turpentine—which latter drug he believes to be especially valuable in every form of puerperal fever.

Dr. Charles Warrington Earle, of Chicago, Ill., presented

A STUDY OF CERTAIN QUESTIONS IN CONNECTION WITH PUERPERAL FEVER, WITH PARTICULAR REFERENCE TO THE USE OF THE INTRA-UTERINE DOUCHE AND CURETTE.

After a discussion of various theories, he concluded that puerperal fever was in every instance produced by infection from without. There was no such thing as autogenetic infection. No one could now disbelieve the germ-theory. Experience had shown that it was impossible for decomposition to occur without the presence of bacteria. There were many ways and many forms of infection. In a larger number of cases than we would suspect, débris bits of placenta, decidua, etc., were left in the uterine cavity, which were, in our present modes of practice, infected by patient, nurse, or doctor.

The only rational treatment was to remove all decomposing material, and prevent a local poison from invading the entire system and producing general sepsis.

Any marked rise of temperature in the puerperal woman should be investigated, and, if not plainly due to other causes, the genital tract should be suspected. A vaginal and uterine douche not reducing it, the uterus should be curetted, using a large, blunt instrument with all antiseptic precautions and great gentleness; the curetting to be followed by an intra-uterine douche to carry away all loosened shreds.

The author cited many cases where the curetting had been done with the most gratifying results, and in no case did he know of any harm resulting from it. He did not wish to be understood as advocating the indiscriminate use of this measure, it being indicated only in those cases where the high temperature persisted after an intra-uterine douche, when it was extremely valuable.

Dr. R. Lowrey Sibbet, of Carlisle, Pa., read a paper on

THE PREVENTION OF PUERPERAL FEVER.

The contagium was always from without, and was never autogenetic. It was carried always by the medical attendant or nurse. Aseptic cleanliness on their part was the best prophylaxis. He had always kept a disinfectant on his washstand, and had never lost a case of puerperal fever. He did not believe in the intra-uterine douche in private practice; it was dangerous, and could not be trusted to an unskilled nurse.

Dr. Doléris, of Paris, France, thought that in practice we were ahead of theory. He used the douche and the curette, or the milder intra-uterine brush, in cases such as Dr. Earle had indicated. He had used these measures with the very best success in many cases, from the second to as late as the seventeenth day.

SECTION IN SURGERY.

Wednesday, September 7th—Third Day—Morning Session.

Dr. W. N. Hingston, of Montreal, Canada, discussed Dr. Maclean's paper of the preceding day. He remarked that he agreed with him in all but one thing, viz., regarding abdominal section. He had operated in three cases; in two of these cases he had made the abdominal section, and both patients died from shock. In the second case he performed the lumbar incision and the patient survived, and there was but little disturbance of the system after the operation. The speaker considered the lumbar incision advisable in all cases where possible.

Mr. Edmund Owens, of London, England, thought there were three factors which should guide us in the operation.

If there was a doubt about the operation, it should be done through the abdominal wall. Again, the size of the tumor must be considered. And in what line of the profession is the operator called, gynecology or surgery. This latter will often decide the point according to the ground he is apt to go over.

Dr. Hardy, of Indianapolis, mentioned a fatal case where the median incision was made.

Dr. F. Lange, of New York, used the lumbar incision; and if the tumor was too large to be removed, he thought it a good plan to incise it and perform a second operation when it had been reduced.

Dr. Maclean, in conclusion, remarked that perhaps he was not quite understood, as he had distinctly stated in his paper that where the lumbar incision could be performed it was preferable. In the cases he mentioned he had no choice. His first case the speaker thought was an ovarian tumor, and naturally made section in the median line.

Dr. Richardson, of Boston, read a paper on

GASTROTOMY FOR FOREIGN BODIES IN THE THROAT.

A patient (male), thirty-seven years of age, was presented to the Section, from whom the doctor had removed a plate with four teeth attached from the lower portion of the œsophagus, about one and one-half inch from the stomach-entrance, by performing gastrotomy. When first seen by the doctor he could discover no obstruction, but the man was, however, retained in the hospital. He was finally discharged apparently well, the pain at the point indicated by him having subsided, and he was able to eat his meals. Eleven months later he returned very much emaciated, the pain returning and being much more severe; gastrotomy was decided upon and the operation performed, the opening being made large enough to admit the hand; the plate was then discovered in the location stated. Owing to its long retention a small abscess had formed there, which subsequently ruptured, the patient making a rapid recovery.

The speaker remarked that had he been certain the plate was there, he was positive he could have removed

it with the forceps; but the difficulty lies in locating, and also the location of the cricoid cartilage and the cardiac opening. He had operated in sixty cases, and found the average distance from the incisors to the cardiac opening to be fourteen and one-half inches; the longest was seventeen inches, and the shortest ten and one-half inches.

The writer described accurately, on the black-board, the anatomy of the parts and location of the plate removed; showing that by gastrotomy or œsophagotomy the œsophagus would be reached at all points with ease.

Dr. F. S. Dennis, of New York, presented some specimens of *scarlet fever bacilli* sent by Professor Lee, of Edinburgh. He then read a paper on

AMPUTATION OF THE HIP-JOINT FOR SARCOMA.

The case was quoted in order to induce surgeons to report such cases and the results. Out of twenty-eight cases of sarcoma of the thigh, only two were living.

The case at present was a young man seventeen years of age; family history was excellent. Five months before entering the hospital the swelling in the left thigh commenced; it had been aspirated, and ten ounces of fluid removed. The tumor when seen was ten inches in length, and twenty-seven in circumference, the inguinal glands were slightly enlarged.

The diagnosis of sarcoma was made, and amputation at the hip-joint was decided upon. No elastic bandage was applied to the leg, but a strong rubber band was passed around the thigh above the joint, which controlled all hemorrhage, and the operation was a bloodless one. On the sixth day the dressings were removed, and the wound was found to have united by first intention; temperature did not rise over 100°, and only reached that point on one day.

The points worth noting are: (1) this patient had a sarcoma, with no hereditary taint; (2) there was no exciting cause; (3) the great rapidity of the growth; (4) absence of metastasis; (5) rapid return to health, as the boy is perfectly well now; (6) importance of secondary hemorrhage; (7) unfavorable prognosis in his condition; (8) the diagnosis was confirmed by the microscope in the hands of Dr. Grower; (9) abscess limited to shaft of the bone; (10) absence of a spontaneous fracture of the femur; (11) large size of the mixed cells of the sarcoma; (12) radical removal of the tumor by amputation at the hip-joint, not at the upper third of the thigh.

Dr. Garmody, of New York, read a paper on

THE SURGICAL TREATMENT OF TRAUMATIC INSANITY BY MEANS OF THE TREPHINE.

The speaker reported the case of a young woman who was struck on the head with a brick, causing depression of the skull; she had been trephined shortly after, but ten years later she began to exhibit symptoms of insanity; trephining was suggested by the speaker, and the operation followed out, the space after the operation being three and a half inches by two inches. No elevation of temperature followed, and at the end of twenty-one days she was perfectly rational; the wound united by first intention.

Sir James Grant remarked that the case was an interesting one, and in his experience of brain surgery he had found that the lower type of brain would bear a fracture of the skull much better than those of an intellectual type. He quoted the case of a mill-hand who fell out of a window and fractured his skull. The speaker was sent for, and on his arrival found the man walking about, and yet there was a depression in the back of the skull in which the finger could be inserted; the brain he considered, became very sensitive in educated individuals.

SECTION IN PSYCHOLOGICAL MEDICINE.

Wednesday, September 7th—Third Day—Morning Session.

Professor Mendel, of Berlin, read a paper on

THE ORIGIN OF THE UPPER FACIAL NERVE,

which was illustrated with numerous sections of the brain.

The paper was discussed by Dr. E. C. Spitzka, of New York.

Dr. E. A. Homen, of Helsingfors, Finland, read a paper on

HISTOLOGICAL ALTERATIONS FOLLOWING AMPUTATIONS IN THE PERIPHERAL NERVES, THE SPINAL GANGLIA, AND THE MARROW.

Dr. Homen had two sets of observations, one relating to the effect on the spinal cord after amputations in dogs. In some of them he amputated the hind limb below the knee, in others the hind limb at the thigh, in others the fore limb at the shoulders. He kept some alive three weeks, some for months, and some for a year. He found that the atrophy, besides involving those limbs whose atrophy has been stated by previous observers, chiefly the posterior column, also involved a special cell-group of moderate- or small-sized cells. This cell-group was atrophied when only the posterior roots were eliminated. He concluded that they had a sensory function. In most of his cases the ascending degeneration was very slight and difficult to identify. The second set of his observations related to the changes in the nerve-stumps, and corroborated those of Spitzka and others.

Dr. Homen presented some beautiful photographs illustrating the points he had stated in his paper.

Dr. Spitzka asked Dr. Homen more particularly as to the location of the degenerated area. He referred to the fact that in some cases a part, in others the whole of the hind leg, in still others the whole of the fore leg, had been amputated; the area of secondary ascending degeneration must have been different in each case. It seemed to him that in the last-mentioned case the degeneration should be in the comma-shaped field, in the former two in special parts of the column of Gall.

Dr. Homen replied that, on the whole, he supposed that expectation would be realized, but where he had succeeded in tearing out special posterior roots their number had been too few, and the consequent degeneration too slight, to permit of very accurate and positive location.

Dr. Otto's paper on

NUCLEUS-STAINING BY ANILINE DYES

was next read, and was not discussed.

Dr. J. Langdon Down, of London, England, presented a paper entitled

CASES ILLUSTRATING THE ASSOCIATION OF THE PROW-SHAPED CRANIUM WITH NEUROTIC DISEASE,

and cited several interesting cases which had come under his observation. The paper was not discussed.

Afternoon Session.

The afternoon session was almost entirely occupied in the discussion on

SYPHILIS IN ITS RELATIONS TO INSANITY.

Dr. Savage, of London, England, opened the discussion. He said there were but few new facts to add. The object of his paper was clinical, not statistical. We have to sum up experience after the syphilitic wave of fashion has passed.

His experience resembled that of most others, that severe cases of brain-syphilis follow slight evidences of secondary trouble. Local syphilitic lesions often form

the starting point of general degenerations. He was unable, in many cases, to draw any defining line between true general paralysis and degeneration following cerebral syphilis. He believed that in some cases general paralysis depends on syphilis for its origin; but does not believe it to be anything like a universal cause. Idiocy, imbecility, and moral perversion due to congenital syphilis, he thought, was rare; most men connected with idiot asylums consider that but few idiots have congenital syphilitic histories. Other physicians, like Dr. Bury, think a fair number of cases are due to this disease. Many syphilitic children die in utero and early life. Syphilis may produce idiocy by causing disease of the envelopes of the brain, or of the brain itself, or by causing destruction of the organs of sense. Syphilis may cause epilepsy in children, and thus lead to idiocy. Some children of syphilitic parents are morally weak, and others break down in critical periods in development. To this last class belong the children of some general paretics.

Discussion then followed upon these two points in Dr. Savage's paper.

Dr. E. D. Ferguson, of Troy, N. Y., instanced a case of general paralysis in a male patient who, near the time of his marriage, had contracted syphilis; which, on account of his previously correct life, was not suspected, and went on to a considerable extent before specific treatment was resorted to; when syphilis was finally suspected and treatment actually entered upon, the patient had become insane. At all times, after he had contracted the disease, he had suffered from great mental depression and mortification; he could never get over the sense of shame. At the post-mortem there were found gross lesions of the membranes of the brain and of the bones of the skull.

Dr. Hurd, of Pontiac, Mich., had no doubt that a true syphilis will produce the simpler psychoses like mania and melancholia. He cited a case that had come under his observation, of what appeared to be acute mania, and a short time after admission it was discovered that she suffered from syphilis. She had the syphilitic rash, the rise in temperature, and these and other symptoms lasted several weeks. She was at once put upon treatment, with the effect of alleviating the symptoms, and there was a corresponding improvement in her mental condition. There was at all times, however, a tendency to relapse of the syphilitic troubles. The disease went on and displayed characteristic constitutional symptoms. After two or three years' treatment the syphilitic trouble was finally in such a state of abeyance that the girl was sent home on trial, and has remained at home nearly a year. The doctor had no doubt that she would sooner or later be returned to the asylum, in consequence of the syphilitic trouble lighting up again.

Dr. C. H. Hughes, of St. Louis, Mo., said syphilis manifests this peculiarity in the neural tissue—it produces abneural changes rather than changes within the structure of the nervous texture. This explains the facility with which syphilitic mental aberration is removable under adequate and vigorous specific treatment. He had seen syphilis often remain without manifestation for years after insanity, and finally develop in locomotor ataxy. We know there is such a thing as syphilophobia, and that it may exist without the pre-existence of any syphilitic poisoning. Syphilitic general paralysis, he had no doubt, was exceedingly common as the result of this poison.

Dr. W. W. Godding, of Washington, D. C., said he had never seen any mental symptoms whereby he could diagnose a case as syphilitic insanity. He cited the interesting case of a girl in his hospital, who came to him about nine months since in the most advanced stage of dementia. Syphilis was only suspected after she had been in the hospital some time and had remained profoundly depressed. She was placed at once upon specific treatment, with the effect of bringing about an immediate change for the better, and she is to-day in a very comfortable condition of bodily and mental health.

Dr. Spitzka, of New York, referred to a febrile condition in secondary syphilis which is complicated with acute delirious mental disturbance. This he believed was a very rare thing. He had seen one case seven years ago, and had not seen anything written upon the subject since that time. The discovery had been made by Finger that during the roseola there was abolition of the knee-jerk. Finger had reported 61 cases in which the knee-jerk was absent.

Dr. E. N. Brush, of Philadelphia, said that two cases of syphilis were now under his observation, which served to confirm the statement of Finger. One of these cases had a short time ago a remission of symptoms of acutely maniacal excitement. He had been quiet and coherent, had parole of the grounds. For five days was very much excited, and there was a very slight return of the knee-reflex, which had previously been entirely absent. He tore his clothing, had hallucinations, and disturbances of sight and hearing. The doctor did not believe we should adopt the term syphilitic insanity.

Dr. T. W. Fisher, of Boston, Mass., cited the case of an officer in one of the hospitals at Boston, who contracted syphilis, and suffered from a great sense of mortification, and went into a state of apprehension and sleeplessness, and finally developed delusions of suspicion. Under asylum-treatment he recovered after the syphilitic symptoms had disappeared.

Dr. Brown, of the Asylum for Feeble-minded Children, at Barre, Mass., was glad to be able to support the ground taken by Drs. Savage and Down in reference to very few imbecile children having congenital syphilitic histories. In his experience of thirty-five years he had noticed but one and one-half per cent.

Dr. Savage said he agreed with Dr. Godding that there was no such thing as syphilitic insanity. You might speak of a specific cause of asthma, and give it a title accordingly. The less said about syphilitic insanity the better, in his opinion. As to the cases recorded of the febrile disturbance of constitutional syphilis, he was glad to note that it was, after all, not so uncommon, although it had hitherto been hardly recognized.

Dr. Savage then proceeded to the next branch of the discussion,

INSANITY DUE TO ACUTE SYPHILIS.

Such cases are rare. Probably some acute cases follow the delirium which may follow with the rash. Many lunatics exhibit venereal diseases contracted while insane. Insanity may follow the onset of secondary symptoms of the more severe type—thus, with optic neuritis, with ulcerations about the face—or it may appear with the onset of local paralysis of the third or other cranial nerve. It may occur with the neuralgia or sleeplessness of syphilis. The disfigurement may cause insanity. There are cases in which syphilis has acted as a moral cause and has set up a form of hypochondriasis.

Dr. Savage next passed to

SYPHILIS PRODUCING EPILEPSY, WITH OR WITHOUT INSANITY.

The epilepsy may be the chief symptom or only a sign of widely spread disease, or it may be a symptom of general paralysis, or of locomotor ataxy. The doctor said cases of epilepsy had come under his observation with a syphilitic history, in which he had not been able to find coarse lesions, as had been claimed to exist by Ferrier and Hitzig.

Dr. Hughes asked Dr. Savage if in his post-mortems he had been unable to find foci, either vaso-motor or vascular changes, microscopically.

Dr. Savage answered that the arterial disease was so general that he had not been able definitely to say that on the left side there was more arteritis than on the right.

Dr. Savage also said there was a good group of cases in which

PROGRESSIVE WEAK-MINDEDNESS

follows constitutional syphilis. It may be preceded by some motor symptoms, by either the ocular motor trouble, a monoplegia, or hemiplegia, in one by aphasia, and in another with other motor trouble. There was another group in which sensory trouble, some temporary loss of vision or taste or hearing, some aphasia, which may be purely muscular, or some temporary giddiness may be the first symptom, which is followed by progressive degeneration, which is not of the same kind and not to be grouped with true general paralysis of the insane depending upon syphilis.

Dr. Channing asked Dr. Savage how he would classify the cases just described.

Dr. Savage replied that he would classify them as organic dementia; that seemed as good a classification as any.

Dr. W. Channing, of Boston, asked if the term syphilitic dementia could be used, if there were sufficient cases to justify it.

Dr. Savage preferred organic dementia of syphilitic origin.

Dr. Gundry next discussed the question, and cited the case of a most respectable and highly connected young lady whose friends had noticed in her a growing tendency to *double entendres*, to slight smuttiness in conversation, and who were at a loss to account for this. He suspected syphilis, but was not for a long time listened to. Finally, after getting the patient on specific treatment, these morbid peculiarities disappeared.

Dr. Savage next discussed

THE GENERAL PATHOLOGY OF CASES OF INSANITY WITH SYPHILIS.

There may be a moral element in some cases, this being of two kinds, either producing hypochondriasis or true melancholia. Syphilitic cachexia may cause melancholic symptoms. Disease of the vessels, small or great, may produce different sets of symptoms.

Gummata are not so common as one would have expected. Inflammation of the membranes in both young and old may cause disease, such as idiocy or acute insanity.

Whether there are any changes in the neuroglia is doubtful. There are changes produced in the nutrition of the various parts, leaving a form of weakness which may act as a cause of fresh changes that may run an acute or chronic course.

Dr. Spitzka corroborated the conclusions of Dr. Savage. His experience coincided with that of Dr. Savage as to the absence of gummata.

The connection between syphilis and tabes dorsalis was still a mooted question. He gave the case of an actor who had been under his observation for some time. This patient has abolition of both knee-jerks. His disease was at times controlled by treatment, and then recurred. He had had in the course of one day fifty or sixty attacks of a peculiar kind of *petit mal*, in which he lost consciousness for a moment, while coming upon the stage oftentimes, but so briefly that he could recollect himself. In one case, where he had to cross a foot-bridge, he had an attack in the course of passing over, but went on as if nothing had happened, the *petit mal* losing its character as a loss of consciousness and becoming replaced by a peculiar sensory disturbance. He found that, accompanied by the prodromal feeling, all the faces of the audience were exactly the same. This sensation passed like an electric flash. He still has these peculiarities, although they are becoming rarer. They are a matter of interest to the patient himself, and he observes their course and peculiar symptoms.

After the reading of a paper by Dr. Ingram, of Washington, D. C., on

GUNSHOT WOUND OF THE SPINAL CORD,

the Section adjourned until Thursday at 11 A.M.

GENERAL MEETING.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY.

Dr. A. Y. P. Garnett, of Washington, offered the following resolution, which was unanimously adopted:

Whereas, It is proposed to hold at the City of Washington, in 1892, an international celebration in honor of the 400th anniversary of the discovery of America by Christopher Columbus, and an exposition of the history, arts, and industries of all nations;

Resolved, That the International Medical Congress favors this patriotic movement, and commends it to the nations of the world.

Dr. A. L. Gihon, United States Navy, offered the following resolution, which was adopted at the general session on Wednesday:

Resolved, That the President of the Congress be authorized to appoint a committee, to consist of an equal number of members from each nationality represented in the Congress, for the purpose of selecting the place of meeting of the Tenth International Medical Congress, to be held in the year 1890; which committee shall report on Friday morning, immediately before the address of Dr. Brandford.

The following committee was appointed on Thursday to name the next place of meeting of the Congress:

Argentine Republic—Dr. Villa, of Buenos Ayres.
Austria-Hungary—Dr. Faskas, of Budapesth.
Belgium—Dr. Gervais, of Antwerp.
Brazil—Dr. Freire, of Rio de Janeiro.
China—Dr. Boone, of Shanghai.
France—Dr. Landolt, of Paris.
German Empire—Dr. Martin, of Berlin.
Great Britain—Dr. Pavy, of London.
Italy—Dr. Semmola, of Naples.
Japan—Dr. Saiga, of the Imperial Navy.
Mexico—Dr. Alvarado, of Mexico.
Russia—Dr. Reyher, of St. Petersburg.
Spain—Dr. Lalearda, of Seville.
Sweden and Norway—Dr. Tillman, of Halinstadt.
Switzerland—Dr. Cordes, of Geneva.
Turkey—Dr. Post, of Beirût.
United States—Dr. A. L. Gihon, United States Navy.
Egypt—Dr. Grant (Bey), of Cairo.

Dr. P. G. Unna, of Hamburg, Germany, then delivered a general address in German on the

RELATIONS OF DERMATOLOGY TO GENERAL MEDICINE.

He endeavored to prove that every general practitioner has the greatest interest that dermatology should be more deeply and more extensively studied. Dermatology, as a special branch, is still young, and has not yet passed the state of formation. The immense difficulties in the way of the study of diseases of the skin, which have up to this time disturbed its continuous development, are in great part well founded, as well in the external position of this organ as in its complicated structure. The author demonstrated these complications in detail, showed the differences in the appearance of the symptoms according to regional differences of the skin, the changes in symptoms in the course of the development of skin diseases, the varieties produced by external agents, the influence of climate, season, nature of countries, of races, sex, and age. Among the external agents the parasites, according to our present knowledge, occupy the most prominent place.

These difficulties will in future be overcome only by minute analysis of each of the several symptoms of skin diseases. All progress in this direction will be of the greatest value for general pathology and therapeutics,

because these facts are proved in the human tissue by means of the naked eye. Dermatology, studied properly, will advance all other parts of medicine—internal medicine as well as surgery—occupying a middle ground between them. Unna recommends, in place of experiments on animals for pathological and therapeutical experiments, to use the human skin, and showed by several examples how this method has led already to the knowledge of new facts. The endowment of new chairs and of separate private laboratories is not sufficient for a thorough investigation of skin diseases. Unna recommends the establishment of a central institute, where noted scientists work together, where all means and methods of study are condensed. Then dermatology will be raised to the rank of one of our most important specialties in medicine, and it will contribute largely to the progress of knowledge in all branches. Finally, the speaker expressed the hope that the United States, always so liberal in the promotion of science, will be the first to develop this ideal.

(To be continued.)

INTERNATIONAL CONGRESS NOTES.

The scientific work of the International Congress was diversified by some interesting incidents of a personal and, at the same time, cosmopolitan nature. A gentleman from the oppressed districts of Ireland found himself insulted at not having been invited to the medical editors' banquet. Consequently he withdrew from the Congress, after drawing proper public attention to his wrongs.

A California dentist claimed that he could transplant teeth—a claim which is well known, in this country at least, to be capable of abundant support. But a British dentist denied the possibility and called for a demonstration. This, we understand, was given to the satisfaction of the foreign guest. The odontology of the West is triumphant.

The Semmola-Durante incident was embarrassing, and at one time seemed to be serious. Matters were smoothed over, however. Dr. Durante presided while Professor Semmola spoke. Then there was clasping of hands and general applause. The spectacle was calculated to fill one with a sense of the true goodness and amiability of the human heart.

All the doctors' wives were charmed by the beauty and grace of the wife of the President of the United States, and the elegant reception which the Chief Magistrate and his accomplished wife gave to the members of the Congress will long be remembered as one of the social events of the occasion. Its complete success was marred only by the astounding brazenness with which the public made their way into the line, to the discomfort and the displacement of those who were entitled to be regarded as guests.

The contributions which have been made to the proceedings by our foreign brethren have received high commendation.

The banquet of the Association of American Medical Editors, given at the Riggs House on Monday evening, was a brilliant entertainment, and amply illustrated that the knights of the quill and scissors can, without special detriment, work until cock-crowing time in pursuits other than those strictly medical.

Every nook and corner, and also a few niches, in the fair city of Washington was occupied by a doctor.

The last arrivals of steamers brought a goodly number of foreigners, so that before the Congress closed a large delegation was present. "By Jove! you know, I was the first to go down after we left Queenstown; and then, you know, the most astonishing thing is that you can't help it."

It is deeply to be deplored that the slimy, cloven-footed ethical question should have been dragged into the proceedings of this Congress. A member of the Council of one of the Sections was made a target. He resides west of Albany and east of Buffalo in the State of New York. He was ousted by the cunningly devised machinations of one who has become popularly known as the ready consultant with homœopaths in their capacity as nurses, and the influence which was exerted upon the valetudinarian element of the Executive Committee enabled that august body to aid in accomplishing the nefarious purpose of the original instigator.

The immense (40 × 30 in.) photograph of the International Medical Congress held in London, elegantly framed and placed on exhibition in the parlor of the Riggs House, by The Medical Record, attracted groups of admirers.

The reception and dinner given by Dr. A. R. Robinson, of New York, President of the Section in Dermatology, at Willard's, to the foreign and American dermatologists and a few guests, on Wednesday evening, was one of the highly enjoyable entertainments of the Congress.

The grand banquet given at the Pension Hall was a great fête. Special precautions were taken to prevent those who, without rights, manners, and cerebral gray substance, insist on gratifying their curiosity from being in attendance. To a commendable degree the plan was successful, and the Committee of Arrangements are entitled to the thanks of the members of the Congress.

The receptions given on Wednesday evening by the citizens of Washington were brilliant and most hospitable. Washington at this season of the year is nearly empty of its wealthiest citizens and those whose open doors always offer a hearty welcome on festive occasions, but the pleasures of the evening were greatly enhanced by the sumptuous entertainments given to the members of the Congress by those who were at home.

The reception at the President's was mismanaged in some way, and was hardly a success. The buffet lunch of five thousand doctors at the Pension Office was, however, an agreeable and satisfactory affair. The doctor is always at home at a buffet lunch.

We note the enterprise of the local Washington papers in publishing good likenesses of the officers of the Congress.

The next meeting of the Congress will be held in Berlin, in 1890, and Virchow is named as its president. This decision will meet with universal satisfaction.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 10, 1887.

THE MEETING OF THE INTERNATIONAL MEDICAL CONGRESS.

THE Ninth International Medical Congress opened under favorable auspices. The beautiful city of Washington had within its borders one of the largest gatherings of medical men ever assembled for a single purpose. The delightful autumnal weather could not be surpassed. The good feeling engendered by a warm, bounteous hospitality prevailed everywhere, and when the crowning pieces were placed upon the preliminary work, through the selected words of the President of the United States and the scholarly welcome pronounced by the Secretary of State, the vast assemblage gave unmistakable evidence of its high appreciation of the labor that had been inaugurated.

The full lustre of international courtesies was shown in the pleasing responses, to their most cordial reception, made by the distinguished representatives from Great Britain, France, Germany, Italy, and Russia.

When the moment arrived for President Davis to enter upon the discharge of his duties, it became doubly manifest that the labor of the Secretary-General had been most exacting, but that it had been systematically and completely performed. His report showed that there was no unfinished business upon his table.

The ceaseless and untiring efforts of the Chairman of the Committee of Arrangements, also, became apparent, as well as the critical diligence of the Chairman of the Executive Committee, who gracefully acknowledged the excellent work done by the original committee on organization.

Numerically the Congress was a success. Of its scientific merits the reader can become fully informed through the medium of our reports and the forthcoming volumes of the transactions.

The number of foreigners present was not large, but it included several distinguished representatives.

The President of the Congress, in his address, paid a graceful and worthy tribute to the memory of the lamented Flint, and then gave a summary of the benefit which would arise from a collective investigation of disease, together with the medical study of the meteorological and other conditions under which diseases occur.

The social entertainments provided for the members of the Congress and their families were bountiful and acceptable. The most noteworthy were the informal reception given by the President of the United States at the White House, and the banquet at the United States Pension Hall. The receptions given by private citizens were exceedingly brilliant, and the lawn-parties and the excursions furnished ample opportunity for those who wished to discard scientific pursuits to find agreeable occupation for all their leisure hours.

Our report of the proceedings of the general meetings, and of the meetings of the sections, of the Congress, was prepared by gentlemen skilled in each department, and we venture to state that for accuracy and fullness it is unequalled in the history of medical journalism.

It has been our aim to give as condensed, and yet as complete, a report as the magnitude of the proceedings would allow, and no pains have been spared in making it comprehensive as well as concise.

Our readers will have discovered that we have been compelled to issue a triple number this week, and nearly or quite as much space will be required for the next number. Our regular contributors, therefore, must patiently withhold their criticisms because of the delay to which their papers will necessarily be subjected.

Of course, it was not reasonable to expect that there would be unalloyed satisfaction throughout the entire meeting of the Congress. Such, in the very nature of the case, could scarcely be hoped for. The number of opinions on a mooted point is necessarily so large that absolute agreement is rendered impossible.

But the withdrawal from the Congress of one of the foreign representatives must be deeply deplored, and that he should have had cause to take umbrage at the supposed humiliation that he had been forced to receive, is profoundly to be regretted.

THE CONDITION OF THE CROWN-PRINCE OF GERMANY.

FROM a special cablegram sent to THE MEDICAL RECORD by Dr. Myles, of London, chief of Dr. Mackenzie's clinique, we learn that the Crown-Prince of Germany has received great benefit from his stay in the Scottish Highlands, that there has been no further recurrence of the growth, and that the disposition toward local congestion is less frequent and more transient.

THE MEDICAL CONGRESS AND THE PUBLIC.

IT is a matter of some interest to observe the tone of the lay press regarding the International Medical Congress just held at Washington. It seems as if the gathering together of some five thousand educated men for purposes of advancing human knowledge, would be a matter of considerable contemporaneous interest. It is, however, always difficult to get the daily press to treat medical conventions with any great amount of seriousness, and this Congress has not been a marked exception. Most of our esteemed contemporaries have devoted vastly more space to the gossip of play-houses, and to incidents of an erotic or criminal character, than to the work of the medical gentlemen at Washington. The editorial discussions, where such have been undertaken, have been gently facetious, or patronizingly critical. It has

been officially telegraphed that the doctors were a fine-looking set of men, and the fraternizing of so large a number appears to have excited a good deal of mild astonishment. Yet it is sagely observed by one paper that there was more bigotry in the International Congress than could be found in any other collection of educated men, not even excepting clergymen.

We cannot, however, complain of all this. Medicine is a technical science and the questions with which it deals only interest the people when some practical application is reached. We have not in this country a physician with the eloquence of Paget, or of the political importance of Virchow, to lend their help in illuminating the somewhat darksome paths of iatric discussion. Medical conventions must be content to do their work with faithfulness and receive their rewards at the hands of the profession itself—which was never more quick than now to recognize merit, or to see through the pretensions of charlatanry.

THE NINTH INTERNATIONAL CONGRESS.

It has already been recorded that the Medical Congress at London was the most scientific, that at Copenhagen the most hospitable, and it will now go down in history that the Washington Congress was the biggest one of all that have been held.

This bigness is generally thought to be a peculiarly American quality, and therefore opportunely fits itself to this last international meeting. The Fifth and Sixth Congresses had a membership of less than five hundred. At the London Congress there were 3,182, and at Copenhagen over seventeen hundred. The Washington meeting is credited with an attendance of over five thousand. There were over a thousand foreigners at London, and nearly thirteen hundred at Copenhagen. The small percentage of foreigners at Washington was due in part, of course, to the long distance which separates us from Europe.

When, three years ago, the invitation to hold the Congress at Washington was delivered at Copenhagen by Dr. Billings, he referred somewhat facetiously to the dangers of undertaking to run a daily paper in a weakly town. It must be confessed that there was a slight suggestion of the aptness of this remark at Washington during the week past.

The managers worked heroically, but five thousand persons of medical education and somewhat erythritic temperament is a large number, and a good deal of friction was inevitable. We think the officers of the Congress deserve much credit, on the whole. The reward properly due to their labors and anxiety will hardly be received by them in this world. Doubtless this was not expected when the management was taken from the hands of the first organizers of the Congress.

The social features of the meeting were, by necessity, much inferior in attractiveness to those of its predecessors. Four or five thousand people cannot be individually and enthusiastically welcomed or comfortably dined and entertained at Washington in September. We recall the feeling words uttered regarding the Copenhagen Congress at its conclusion:

"By the king and his subjects the professors of medicine were honored as they have never been honored in any country. We have had a veritable feast of reason and a flow of soul. Only in a true civilization could medicine have been so received!" Such an encomium is in strong contrast to the reception of the Congress by our Government.

We believe, however, that our foreign guests have seen that their American hosts were hospitable to every extent in their power.

The scientific work of the meeting was respectable, though falling much below the average of the two preceding Congresses. It is impossible to deny the fact that the representation of distinguished foreigners was extremely small; and the best contributions were decidedly from American physicians.

In conclusion, we venture the opinion, which must rise inevitably in unprejudiced minds, that the Ninth International Congress was far from being a failure, but still further from being a brilliant success. From an international point of view it was tremendously lopsided, being made up largely of the West, still more from the South, with a touch of the East, and a Continental sprinkle from Europe. The general character of it was much as it had been predicted it would be. But it is over now, not without credit, and we trust that peace and harmony will reign.

News of the Week.

The Wisconsin State Dental Society, at its annual meeting, held in Milwaukee in July, passed some stringent rules against advertising, and prescribed that all new dental appliances invented by members of the Society must be brought before the whole body, and opportunity given for a discussion of their merits. Some of the members are said to have objected so strongly to the new regulations that they withdrew from the association.

Dr. T. Y. Sutphen, of Newark, N. J., was elected a member of the American Ophthalmological Society at its last meeting.

The Berlin papers report that Dr. Morell Mackenzie has sent his bill to the Crown-Prince for his two visits to Berlin. The bill amounts to the sum of 2,500 guineas ($12,500).

The New York City Board of Health has recently been reorganized by its President, Mr. Bayles. The same officers are retained, but in many cases their positions and work have been changed.

The following resolutions have been adopted:

Resolved, That Dr. E. G. Janeway, Dr. A. Jacobi, Dr. C. R. Agnew, Dr. Stephen Smith, Dr. Daniel M. Stimson, and Dr. Joseph O'Dwyer, be and are hereby requested by the Board to act as a Consulting Medical and Surgical Board of the Willard Parker Hospital and of other hospitals of this Department in East Sixteenth Street.

Resolved, That provision be made by this Board to refund quarterly during the coming year, to the physicians of this city who may be engaged in private prac-

tice, the amounts that may be expended by them for postage in reporting births and contagious diseases to this Department.

Resolved, That the recommendations of the Sanitary Superintendent for securing a full registration of births be approved, and that he be directed to take the necessary measures to enforce a proper reporting of the same to this Department.

The above are calculated in many ways to add to the efficiency of the Board. The recommendations regarding the registration of births are eminently practical and timely, as it is estimated that at least twenty per cent. of the births occurring in this city are not reported. The ability of the Board to remunerate physicians for postage, etc., will possibly depend upon the amount which may be allowed by the Board of Apportionment for that purpose. There is every argument in favor of it, however, and it is, in fact, the only condition which will insure prompt and faithful reports.

The Antiseptic Value of the Essential Oils.—In the *Annales de l'Institut Pasteur*, No. 4, April 2, 1887, M. Chamberland examines the action of essences on the bacteria of charbon, and on many other less known microbes. The number experimented upon was 115; only 14 allowed the development of the charbon-bacillus in yeast-water saturated with their vapor. Among these was essence of cloves, which is sometimes used to arrest dental caries. But out of 102 essences that by their presence prevent the development of the organism, only 8 seem to kill it definitely, for it usually revives as soon as the essences have evaporated. The essence of cinnamon alone appears completely to destroy the germs in four days, while bacteridian germs placed in fresh yeast-water have been cultivated after having been for four days in contact with other essences. Essence of China cinnamon does not stop the development of filamentous bacteria, but essence of vespetro seems to kill it completely in eighteen hours. Placed in contact with carbuncle-bacillus, or its germs, in solution (essence ½ c.c., alcohol 10, saponine solution at 1–100th, 20, water 70), seven essences kill that bacterium in doses varying from 1–13, 200th to 1–24, 200th. These essences have about the same antiseptic power as sulphate of copper. Among these seven essences are three of great antiseptic power, either in solution or in vapor: Essence of China cinnamon, of Ceylon cinnamon, and of origanum. The essences must be used fresh; when they become oxidized by exposure to air, they lose part of their properties. M. Chamberland next compares the antiseptic action of thymic acid and of different metallic salts upon bacteria. The bichlorides of mercury, and of ammonia and nitrate of silver, act at a strength of 1–80,000th; after these come thymic acid, persulphate of iron, chloride of zinc, etc. In order to study the antiseptic power of certain substances upon organisms in general, he prepared solutions of these substances at 1–100th, of which he poured 1 c.c. into a series of small flasks containing severally 5 c.c., 10 c.c., and 20 c.c. of neutral yeast, which gave him solutions of 1–600th, 1–1100th, and 1–2200th; to each of these he added ½ c.c. of washings of garden-soil. He found that the most energetic antiseptics were sublimate of mercury and thymic acid. Sulphate and acetate of copper and bichromate of potash, although very active, allowed vegetations to grow; next to them in power were China cinnamon, persulphate of iron, carbolic acid, alum, and sulphate of quinine. Boric acid, hyposulphite of soda, salicylate of soda, arseniate of potash, bisulphide of soda, chloride of alumina, and chloride of lime are comparatively weak antiseptics.—*British Medical Journal.*

The Progress of Medical Science in Roumania.—It may be said, in a general way, that the cultivation of science in a country goes hand in hand with that country's advance in prosperity, and with the happiness and well-being of its citizens. If such be the case, far-off Roumania is to be congratulated upon its progress. The activity of its medical and scientific men is well shown in the character of the articles published in its journals. One of the oldest, if not the oldest, medical journals is *Spitalul*, now in its seventh year, published monthly at Bucharest, in the Roumanian language. But this language, though allied to the other Romance tongues, is so little known to the western nations of Europe that the articles there published are long in seeing the light, and this has led to the establishment of journals printed in other languages. The *Bulletin de la Société de Médecins et Naturalistes* is published monthly at Jassy, in both French and Roumanian. In July of the present year there was begun the publication at Paris, and wholly in French, of the *Archives Roumaines de Médecine et de Chirurgie.* The editor is Dr. Georges Assaky, Clinical Professor of Surgery at Bucharest. The journal is to appear every two months.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 28 to September 3, 1887.

Smith, Joseph R., Lieutenant-Colonel and Surgeon. Ordered to report in person to the Surgeon-General of the Army, on September 2, 1887, on business connected with the public service, and on completion thereof to return to his proper station. Par. 9, S. O. 198, A. G. O., August 26, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 3, 1887.

Dean, Richard C., Medical Director. Detached from duty as member of Examining and Retiring Boards and ordered to the Naval Hospital, Chelsea, Mass.

Peck, George, Medical Director. Orders as delegate to International Medical Congress revoked.

Simons, M. H., Surgeon. Detached from the Constellation and ordered to the Naval Academy.

Rogers, B. F., Surgeon. Detached from Marine Rendezvous, New York, and ordered to the Alliance.

Field, James G., Assistant Surgeon. Detached from the Vermont, and ordered to Marine Rendezvous, New York.

Henry, C. P., Assistant Surgeon. Ordered to the Ossipee.

Lumsden, G. P., Passed Assistant Surgeon. Ordered to the Boston.

Atlee, Louis W., Assistant Surgeon. Restored to duty.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 32, No. 12. NEW YORK, SEPTEMBER 17, 1887 Whole No. 880

Reports of Societies.

International Medical Congress.

NINTH SESSION.

Held in Washington, D. C., September 5, 6, 7, 8, 9, *and* 10, 1887.

(Special Report to THE MEDICAL RECORD.)

(Continued from page 361.)

SECTION IN PATHOLOGY.

WEDNESDAY, SEPTEMBER 7TH—THIRD DAY—MORNING SESSION.

THE PIGMENTATION OF THE SKIN AT THE ARTICULATION OF THE PHALANGES IN CHLOROSIS.

DR. POUGET, of Cannes, France, read a paper on this subject, in which he directed special attention to pigmentation of the knuckles, a fact first noticed by Bouchard, of France.

DR. THOMAS TAYLOR, of Washington, D. C., read a paper on the

CRYSTALLOGRAPHY OF FATS,

in which he directed special attention to their condition and relation to health and disease.

THE ETIOLOGY OF LIVER ABSCESS

was the title of a paper sent by DR. KARTULIS, of Alexandria, Egypt, and read by Dr. J. A. S. Grant (Bey), of Cairo.

DR. CHARLES W. EARLE, of Chicago, described

FIBROID DEGENERATION OF THE PANCREAS,

of which he had reported cases, and which was liable to be mistaken for cancer.

AFTERNOON SESSION.

DR. JOHN NORTH, of Keokuk, Ia., read a paper on

THE PATHOLOGICAL RELATIONS OF PTOMAINES AND LEUCOMAINES.

The paper was discussed by Dr. Johnson and Dr. Keller, and was followed by a paper on

TYROTOXICON,

by DR. VICTOR VAUGHAN, of the University of Michigan.

SECTION IN PUBLIC AND INTERNATIONAL HYGIENE.

WEDNESDAY, SEPTEMBER 7TH—THIRD DAY—MORNING SESSION.

THE PRESIDENT read a paper from DR. B. W. RICHARDSON, of London, England, on

THE GROWTH OF PREVENTIVE MEDICINE IN GREAT BRITAIN.

DR. DOMINIGOS FREIRE, of Rio de Janeiro, Brazil, read a paper, which was translated by the French secretary, Dr. R. Le Mounier, of New Orleans, La., on

VACCINATION IN YELLOW FEVER,

the tenor of which was that the disease can be prevented by inoculation with attenuated virus. The paper was accompanied by microscopic specimens of the microbe of yellow fever.

Dr. Freire being asked what was his theory concerning the attenuation of the virus of yellow fever, answered, by oxidation through the red corpuscles of the blood, and the proper or improper medium into which it is placed; but, he added, all this is *as yet* only conjecture.

DR. BAILHACHE, Military Hospital Service, asked if vaccination in one family arrested the progress of the fever in that family?

DR. FREIRE answered in the affirmative, stating that in families of ten and fifteen members, living in *one hut*, if vaccination was practised after the outbreak of the fever among the members not yet affected, that this arrested the further progress of the scourge; whereas, where it was not practised they all were stricken down with the fever and many, if not all, died.

SECTION IN MILITARY AND NAVAL SURGERY AND MEDICINE.

WEDNESDAY, SEPTEMBER 7TH—THIRD DAY—AFTERNOON SESSION (Continued).

The foregoing papers upon this subject (Penetrating Gun-shot Wounds of the Abdomen) elicited a very interesting discussion, in which DR. THOMAS G. MORTON, of Philadelphia, took a prominent part.

The first point to be considered, the speaker said, in the treatment of these wounds, is whether the patient is in a proper condition for an operation; upon this depends the success of many operations. Another point of great importance is the positive knowledge of the existence of a perforation of the intestines or other abdominal organs, or even of a mere penetration of the peritoneum, without such complication. There being no doubt in the surgeon's mind as to these points, he should not, in the speaker's opinion, have the least hesitation in opening the abdomen. There exists, in all cases of penetration, a possibility of loss of blood from some severed vessel, and of the escape of fecal matters into the peritoneal cavity.

The abdomen should always be opened under the strictest antisepsis; through its potent aid the operation is attended with little danger. In cases of stab wounds of the abdomen, with perforation of the peritoneum, he would advise making an incision sufficiently large to enable the surgeon to clearly see what he is doing, and, having secured any bleeding vessels, to wash out the cavity with a warm solution of bichloride of mercury, a $\frac{1}{10000}$ (!), until the water returns perfectly clear, and then sew the wound in the usual way. He preferred, in the great majority of cases, to make the incision over the middle line, except in perityphlitic abscess, when he made a curvilinear incision over the most prominent parts of the abscess. His experience had taught him that a large incision is better than a small one, and safer in every respect. For a gun-shot wound, he proceeded in the same manner. In a boy, seventeen years of age, with a penetration of the transverse colon, and a young negro with a similar injury, upon whom he lately performed this operation, the temperature did not exceed 101° and 102°, respectively, and this for the first day only, recovery being perfect and rapid in both cases.

DR. HENRY JANES, of Waterbury, Vt., asked the speaker how long a time such an operation as he had described usually required.

Dr. Morton, in answer, replied that the time varied somewhat, according to the seat and extent of the injury, but that from one hour and a half to two hours was, as a rule, sufficient.

Dr. Varian, of Titusville, Pa., desired to know Dr. Morton's opinion as to the practicability of performing this operation upon the battle-field.

Dr. Morton, in reply, thought it would be difficult, but that the numerous objections which had been given concerning the impracticability of operating were easily disposed of. In the first place, the probable abundance of pure spring water in the neighborhood with which to prepare the solution of the bichloride—which can easily be carried in the pocket—and the removal of the patient to some field hospital, were, of themselves, conditions which would enhance, rather than diminish, the chances of success. I consider it the surgeon's duty, in the light of recent experience and observation, not to temporize, but to make an effort to save the patient; this operation can do it, while the expectant treatment involves many dangers. I am confident that something can be devised for use on the battle-field; a modified antisepsis is better than no antisepsis at all.

Dr. Daniel Smith Lamb, of Washington, D. C., asked how large a wound would induce the doctor to operate.

Dr. Morton replied that the slightest perforation of the peritoneum was an indication for the operation, for it is well known that these small wounds may be, and are often, followed by grave results. He would take this opportunity to say that he advocated the opening of the abdomen in typhoid fever when perforation of the intestine by ulceration has taken place, as such an operation gives the patient the greater chance of recovery.

The President, Dr. Smith, adverted to the great importance of this subject. What we want, to deduce conclusions for our future guidance, is an accumulation of facts. Dr. Morton, by his remarkable success in these cases, which success was not, it may be confidently asserted, the result of mere chance, and the New York surgeons, with their recent experience, had, he thought, been accumulating such facts very rapidly. In the light of these facts the legal responsibilities of the surgeon should be considered. The President concurred with Dr. Morton in his views as to the possibility of modifying antisepsis to meet the exigencies of the battle-field.

Dr. Moore, of Richmond, Va., after a few preliminary remarks, read his paper, entitled

ON THE TREATMENT OF PENETRATING GUNSHOT WOUNDS OF THE ABDOMEN.

The author gave statistics of cases of this nature and the rate of mortality, and quoted at length from reports of the French and British army.

No surgeon had, in his opinion, had sufficient experience with this operation, which was comparatively a new one, to be considered an authority on disputed points. He spoke of the difficulties of diagnosis of perforation, and advocated the exploration of the wound with some delicate instrument. The incision should be made only sufficiently large to allow a thorough exploration, and the earlier after the reception of injury, barring the occurrence of shock, the greater were the chances for recovery. It is the opinion of Sir William Malcolm that if the operation be delayed twenty-four hours no case ever recovers.

In conclusion, he advocated supporting measures and the use of quinine hypodermatically previous to the operation, to diminish the liability of resultant shock.

Dr. Varian's views were in harmony with those of Dr. Moore so far as civil practice is concerned, but the question still to be discussed was the treatment of such cases upon the field of battle.

Dr. Watson, of Jersey City, agreed with Dr. Morton.

Dr. Bentley, of Little Rock, Ark., dissented from the opinion of Dr. Morton, and regarded the application of the method of treatment as impossible on the battle-field, as it is an operation which requires skill, time, and care. He, however, recognized its value in private and hospital practice, where all the conditions are favorable.

SECTION IN PATHOLOGY.

Thursday, September 8th—Fourth Day.

Dr. Leopold Gervais, of Antwerp, Belgium, reported two successful cases of

REMOVAL OF THE SUPERIOR MAXILLA

for cancerous tumors.

Dr. Jackson, of Norfolk, Va., read a paper on

THE NATURAL AGENCIES EXHIBITING THE LIFE-PROCESSES OF PATHOLOGICAL ORGANISMS.

This was followed by a paper on

THE PATHOLOGICAL ANATOMY OF ALCOHOL,

by Dr. Henry F. Formad, of Philadelphia.

Dr. N. S. Davis, Jr., of Chicago, read a paper on

CELLULAR DIGESTION AND ITS UTILITY IN PATHOLOGICAL PROCESSES.

All these papers were technical and gave rise to little or no discussion.

SECTION IN PUBLIC AND INTERNATIONAL HYGIENE.

Thursday, September 8th—Fourth Day.

A translation of a paper by Tomassi Crudeli, of Rome, Italy, on

FACTS AND THEORIES RELATING TO THE CAUSE, NATURE, AND PREVENTION OF MALARIAL FEVER,

was read and the bacillus described.

Dr. George T. Maxwell, of Ocalo, Fla., then read a paper on

THE INFLUENCE OF CLIMATE ON THE PRODUCTION OF CHOLERA INFANTUM,

in which he took the position that heat was an essential factor in its causation. The general scope of the paper was that the cause of this disease is not yet well understood.

THE HISTORY AND PRACTICAL APPLICATION OF STEAM AS A DISINFECTANT

was the title of a paper read by Dr. A. N. Bell, of New York, which was followed by papers on "The Sanitary Inspection of Railroad and Passenger Cars," by Dr. Harvey Reed, of Mansfield, O.; "Public Hygiene," by Dr. W. C. Cook, of Nashville, Tenn.; "The Clinical History of Continued Malarial Fever," by Dr. B. D. Taylor, U.S.A.; "A New Method of Detecting Trichina Spiralis in Meat," by James A. Close, M.B. (Toronto), F.R.M.S. (London), L.R.C.S.E.

SECTION IN GENERAL MEDICINE.

Thursday, September 8th—Fourth Day—Morning Session.

Dr. Ephriam Cutter, of New York, read a paper entitled

MORPHOLOGY OF RHEUMATIC BLOOD.

Dr. Cutter illustrated his lecture with stereopticon slides. He attributed the increased force of cardiac, with consequent exhaustion and inflammation, to the great adhesiveness of the blood.

Dr. Mariano Semmola, of Naples, Italy, read a paper on the

PATHOGENESIS OF ALBUMINURIA.

The paper was delivered in the French language. He gave the results of original investigations made at the University of Naples.

Dr. Nunn discussed the paper, speaking favorably of the albumen diet.

Dr. Cutter, of New York, regarded the diagnosis of Bright's disease as imperfect unless there were albumen and casts.

NOTES ON THE TREATMENT OF PHTHISIS, MORE PARTICULARLY THAT BY INTRA-PULMONARY INJECTION.

R. Singleton Smith, M.D. (London), F.R.C.P., Physician to the Bristol Royal Infirmary, England, read a paper on this subject. Since the last International Congress at Copenhagen, in 1884, numerous attempts have been made to do more than had previously been attempted for a disease in which the *vis medicatrix naturæ* does so little. The reader of this paper briefly summed up the various methods which have been recently suggested since the discovery of the bacillus of tubercle, and expressed his belief in the possibility of benefit by treatment directed toward the destruction of the bacillary growth. He reported the result of his experience with regard to gaseous rectal injections, and said that in consequence of the absence of all indications of benefit he had given up this method entirely. He alluded to the work done by Professor Pepper, of Philadelphia, and Drs. Beverley Robinson and White, of New York. In carrying out the method of intra-pulmonary injections suggested by these and other workers he had met with partial success in a series of cases reported in the *British Medical Journal*, of 1886.

In consequence of the proved utility of iodoform in chest disease, as shown by a steadily increasing mass of evidence since its first introduction for this purpose by Professor Semmola, in 1878, and supported by a series of cases presented to the International Congress of 1884, in which the author found increase of weight, improved appetite, diminution of temperature, and general improvement under the administration of iodoform given by the alimentary canal, it was thought that iodoform would be the best substance to employ for injection into the parenchyma of the lung. The clinical utility of iodoform being the ground on which its use for this purpose has been founded, the evidence is not shaken by any statistics as to the comparatively feeble powers of the drug as a germicide.

The insolubility of the drug is the chief difficulty; various solvents have been used, but with only partial success. Ether is objectionable, because of its effects on the brain; giddiness and other feelings of discomfort rather alarm the patient, and give rise to an unwillingness to have a frequent repetition of the injections. Eucalyptus oil is irritating, two cases were mentioned in which acute pleuritis, with much pain, rise of temperature, and effusion had followed the injection of an iodoform solution in oil of eucalyptus. The vaseline oil, either alone or in combination with eucalyptol, had also been used, but the author still considers the question what is the best fluid to inject, to be still unsolved. He did not advocate the use of solutions containing free iodine or bichloride of mercury, and he would not in future employ any fluid for injection into the lung which had not previously been tested hypodermically; if it gave rise to much inflammatory irritation in the subcutaneous cellular tissue he would not venture to inject it into the lung. He was of opinion that injections into cellular tissue might possibly be of some little service, although there was as yet not much reliable evidence on this point, but they would serve as a reliable test whether any given fluid was suitable for deep intra-pulmonary injection.

It is true that if iodoform be of use, as the clinical evidence indicates, then it is likely to be of far greater utility when injected, even in small quantity, into the focus of a diseased patch than when given in larger doses diffused throughout the whole body. Such injections have been shown to be not especially hazardous. Even the cases in which pleuritis has occurred had recovered completely from the attack in the course of a few days, and possibly the pleuritis was due to the failure of the fluid to pass beyond the pleural cavity into the lung-substance. Nevertheless, the author would not advocate the use of such injections in cases which were hopeless, neither would he employ them in cases where other and less active measures were accomplishing the object in view. He concluded his paper by urging perseverance in spite of failure, and by expressing his belief that what as yet was only a tentative investigation would ultimately result in numerous and signal successes.

The President made a few very complimentary remarks to Dr. Smith for his valuable paper. He was favorably impressed with Semple's inhaler.

Dr. Truax, of New York, said that he had little faith in iodoform, as he had cultivated the bacillus tuberculosis in its solution.

Afternoon Session.

Dr. Pavy, of London, England, spoke on

DIABETES.

This disease has always been regarded as an inscrutable one. There are still many points open for earnest study and patient investigation. The nature of the disease is that of faulty disposal and assimilation of food, elements. Foods taken into the body are classed as nitrogenous, fatty, and the carbohydrates. It is this latter class that especially concern us in diabetes. Starch-dextrine, lactic- and cane-sugar go to make up this group, and each has an equal action, when ingested, in causing the condition of diabetes.

Normally the carbohydrates are disposed of in the portal vein, from whence they are carried to the liver and there assimilated. Experiments in which defibrinated blood or oxygen have been injected into the portal vein have been followed by marked evidences of sugar in the urine. Similar results have been produced in animals by forced respiration, thereby supersaturating the blood with oxygen. Vaso-motor paralysis of the hepatic vessels, by causing an excess of blood, prevents the proper deoxygenation of the blood, and similarly causes sugar to be present in the urine. This condition allows the carbohydrates to be converted into sugar and to pass through into the general circulation.

In the celebrated experiments of Benard, in puncturing the floor of the fourth ventricle, he also noticed a vaso-motor paralysis of the hepatic vessels. It is noticeable that in those cases of vaso-motor paralysis of the chylopoëtic system where there is a red tongue the disease is more severe, undoubtedly owing to the fact that the paralysis has extended more generally throughout the circulatory system.

In health there is only a faint trace of sugar in the blood and the urine. The latter is always a reliable index as to the amount of sugar in the blood. In diabetes the sugar reaches the blood directly, without going through the process of assimilation in the liver. In health, sugar is stopped before it enters into the general circulation, but in diabetes it is found in the blood directly in proportion to the quantity of carbohydrates taken. Sometimes even in health there is sugar in considerable quantity in the urine, in cases where there has been taken very large quantities of the carbohydrates, showing that there is a normal limit to the assimilative power of the liver, which, if exceeded, will result in a diabetic condition. The liver is a fat- rather than a sugar-producing organ, converting animal starch into sugar and then into fat. The liver is different from other organs in that it has small arteries and large veins. The contents of the portal vein should be in a decidedly venous condition, otherwise we will get sugar into the general circulation.

Diabetes is of a neurotic origin, and it is well established that nervous conditions influence in a material manner the condition of the patient.

In considering these cases the first thing to do is to test for sugar in the urine, and in order that we may

fully appreciate the progress of the case this test should be a quantitative one.

In selecting urine for examination it is necessary to procure both an evening and a morning specimen. It frequently occurs that sugar is only present directly after the taking into the body of carbohydrate foods. It is owing to the fact that specimens of urine are procured at different times and after different conditions of diet that physicians differ so often in the diagnosis of diabetes. Among the various tests for sugar probably the most accurate is the copper test, in the form of Fehling's solution. The great objection is that this solution will throw down a precipitate on boiling, which is very liable to mask the test. In order to obviate this he had had pellets made of the solid ingredients of this solution, in an anhydrous form, such as can be at any time dissolved in water for use.

When patients come to us we should not ask them, but tell them, what they have been eating or drinking. This can be accurately done by the quantitative test. This is best and most easily accomplished by the decolorization test, which is done in the following way:

At the bottom of a long, graduated pipette is attached a tube running into a flask containing a given quantity of a solution of sulphate of copper, differing from Fehling's solution only in containing ammonia and potash instead of the latter alone (in order to prevent the precipitation of the oxide); at the upper part of the flask is placed an escape-tube. At the rubber tube through which the urine escapes into the flask is placed a compressor controlled by a screw, which regulates perfectly the flow of the urine. After the copper solution is brought to the boiling-point, by a flame placed underneath the flask, the urine is allowed to enter the flask, drop by drop, until the copper solution is exactly decolorized. By reading upon the graduated pipette the amount of the urine which has been necessary to decolorize the known quantity of copper solution, we can form a proportion by which an accurate estimate can be made of the contained sugar. By this means we can follow the course of the disease even more accurately than the clinician who, with his stethoscope, watches, from day to day, the progress or retrocession of pulmonary disease.

It is well to note, in passing, that in diabetes we sometimes find albumen in the urine, and this is often present just in proportion as the patient improves or gets worse. A test for albumen, which has no known fallacy, is that with citric acid and the ferrocyanide of sodium. The objections to the nitric-acid test are that it may precipitate either uric acid or the oleo-resins. In the above test, if a pellet of citric acid is dissolved in the urine and boiled, we may then get a precipitate of uric acid, but upon the addition of the ferrocyanide of sodium the solution invariably clears up unless albumen be present.

In considering the disease itself, we find it has different grades of intensity. The liver, in health, has not unlimited control in the assimilative power over the carbohydrates, and diabetes may be said to exist when that power is below the ordinary. When a person first comes to have diabetes, as we have stated, it is through faulty assimilation; it does occur, however, that as the disease progresses, the sugar is formed from the tissues themselves, as is proved by its constant presence when the patient is upon a strictly meat diet.

Age influences greatly the occurrence of the disease. Out of 1,360 cases tabulated, forty-five per cent. occurred between forty and sixty years of age. Age also affects prognosis; young subjects rarely recover, the disease ordinarily terminating in two years. In old people the prognosis is more favorable, many recovering. One reason, possibly, for the tendency of children to do badly is that they take unsatisfactory care of themselves, while elderly persons are oppositely inclined.

Diabetes sometimes commences in a very mild form, and may exist for a long time unrecognized. How do we know it is not recognized? It is said that bootblacks in hotels become expert in recognizing diabetics by the white stains on their shoes and clothing caused by stains from their urine.

Then, too, diabetes runs in families in a very marked manner. One of the most striking instances of this was in a family which came under my observation, where the grandmother, the mother, and four out of her five children died of diabetes.

Recently he had found many cases beyond the middle period of life having pain in their limbs, which were formerly called neuralgia; they also have an irregular gait, somewhat ataxic. They sometimes feel as if they wanted to "gather themselves together," so that they may walk without giving their friends the impression that they have been taking too much. Again, they have the peculiar symptoms of pains in their extremities and "throughout the bones," which are much worse when they get warm in bed. This probably is, or analogous to, a peripheral neuritis.

In treating young subjects we must try merely to stay the disease; we cannot stop it. We take away the sugar, the patient temporarily improves, and believes himself cured. He is borne up only by false hopes.

In young subjects it seems to have a progressive character, not unlike progressive muscular atrophy, or of locomotor ataxia.

For elderly patients we can do much. Appropriate diet is absolutely essential. Sweets, pastry, puddings, and bread must be interdicted, while meat, eggs, poultry, butter, and cheese may be taken. In regard to milk it must be remembered that it contains lactic sugar, and, therefore, also, cannot be taken.

In regard to bread, the gluten and almond breads, especially the latter, are preferable. Gluten bread may be considered of a good quality if containing only thirty-three per cent. of starch. He had found that many times patients paying a high price for their bread got an inferior quality, containing from sixty per cent. to eighty per cent. of starch. Almond is far preferable, containing fifty per cent. of fatty matter, and only seven per cent. or eight per cent. of carbo-hydrates. It was necessary, therefore, to have the proper means with which to carry out the treatment successfully. The medicinal agents which he gave were opium, morphia, and codeia. Whether due to the natural history of the disease he could not tell; but he thought they exerted a restraining influence over the disease.

If the sugar disappears from the urine he commenced to give his patients two ounces of bread daily; if, after a few weeks or months, he still found no sugar, he gave them three ounces of bread, increasing in this manner until he gave them six ounces, with which quantity they must remain content.

If the bread causes the sugar to reappear, it must not be taken.

We have seen that if there is sugar in the urine, it must be proportionately so in the general circulation. An excess of sugar in the blood predisposes to disease. The patient is then "ripe for anything wrong."

Dr. Herrick, of Cleveland, O., asked whether Dr. Pavy considered the condition of the urine the objective point in the treatment, or did he aim his treatment directly to the abnormal condition in the portal and hepatic circulation.

Dr. Pavy said that he looked upon the lessening of sugar as an evidence that the assimilative power of the carbo-hydrate is improved. The urine is an index of sugar plus the power within.

Dr. Arnold, the President, asked whether Dr. Pavy would corroborate the statement that the Hebrew race are predisposed to diabetes.

Dr. Pavy replied that while it was true they were more predisposed, it was also true that they were more amenable to treatment.

Dr. Truax, of New York, asked if Dr. Pavy had found

that where acetic ether was present death followed quicker.

Dr. Pavy replied that he was not a believer in acetonæmia.

Drs. Miller and Holton also addressed questions to the lecturer.

Dr. J. A. Ouchterlony, of Louisville, Ky., moved that Dr. Pavy be requested to furnish a paper for publication, which was voted unanimously.

Dr. Stockman read a paper for Dr. R. W. Phillips, of Edinburgh, Scotland, entitled

THE ETIOLOGY OF PHTHISIS.

He claimed that experiments go to show that ptomaines are the principal etiological factors in phthisis. In experiments where the ptomaines have been injected the animals give all the characteristic symptoms of phthisis, such as sweating, great depression, etc.

Dr. Phillips sent with his paper a tabulated report of experiments with injections of atropine, which, he claims, counteracts the action of the ptomaines.

Dr. Herrick, of Cleveland, said that he believed that the deposits in the lung were excretions from the blood of material which the natural eliminatives were unable to dispose of. He did not believe the bacillus tuberculosis to be the cause of phthisis *ipso facto*.

Dr. Whitmarsh believed that a very large number of the race have tuberculosis; it often lies dormant, yet the germ is there, like fuel, only needing a match to set it on fire. The early stage of phthisis is curable, but, unfortunately, that stage is overlooked.

Dr. Arnold, the President, thought that Koch still had the best side of the argument. The crucial experiment has been made, that when inoculations are made with sputa containing the bacillus tuberculosis, we get phthisis, but do not get phthisis under any other circumstances.

Dr. Truax, of New York, called attention to the additional evidence of the power in the bacillus tuberculosis, viz., that repeated cultures of the germ still retain the power to cause phthisis.

The Secretary read a paper by Dr. W. B. Neftel, entitled

SOME CONSIDERATIONS ON THE PATHOGENESIS OF DISEASES OF WOMEN.

He endeavors to prove, by experiments upon the lower animals, that compression of the chest will cause phthisis. Although his experiments did not prove this, they did show that they would cause albuminuria, which he attributed to venous stasis.

From these experiments he made analogous comparisons of the deleterious effects of wearing corsets and high-heeled shoes.

He suggested that the Congress appoint a commission to investigate the various modes of feminine dress of the different nationalities, and select such forms as are both practical and useful. He thought that in this way, with the sanction of the profession, some impression might be made upon the female sex to change their present mode of dress.

Dr. Herrick thought that experiments upon the lower animals were of little use in forming opinions of disease in the human subject.

Dr. Price, New York, agreed with Dr. Herrick in the main. He did not think that bacilli were the cause of phthisis.

Mrs. Dr. Finlay, Mansfield, O., asked if statistics showed that the difference in dress caused a corresponding increase of mortality among women.

Dr. John Eye, Reading, Pa., thought it very necessary that each air-cell had free play in performing its function, otherwise it would be a favorable soil in which the bacillus could grow. He believes in the germ-theory of phthisis.

SECTION IN GENERAL SURGERY.

Thursday, September 8th—Fourth Day—Morning Session.

Dr. Burney read a paper, on behalf of Dr. Richardson, of St. Louis, on a case of gastrotomy for the relief of foreign bodies in the throat. The speaker also mentioned a case in which he himself had operated, a man having swallowed an ordinary plated case-knife (the latter he presented at the meeting). While playing with his family the knife slipped from his fingers as he pretended to swallow it, and really did. The writer did not believe in the continued suture in this operation, but the interrupted, one and one-eighth of an inch apart.

In discussing Dr. Dennis' paper, Dr. Myers remarked that Macewen used only digital pressure in the amputation of the thigh-joint.

Dr. Maclean, of Detroit, said that Dr. Dennis' method was the principal point in the paper; he had had the best results in Lister's abdominal compressor.

Dr. Weeks, of Maine, stated that he used the ordinary rubber-bandage with a compress, the bandage being four thicknesses and secured much the same as Dr. Dennis'.

Dr. Manley, of New York, thought it difficult to find anything to take the place of Lister's compressor.

Dr. Reyher, of St. Petersburg, said that he had had some unpleasant experiences with Lister's compressor. He was in the habit of first excising the head of the bone, then piercing the thigh and ligating in two parts, then amputating the legs; the flaps were then under the control of the surgeon, and he could work at leisure, but he usually put a rubber-bandage above.

Dr. N. Smith thought that the less tissue left the better, and that he was satisfied with Brodie's operation, the anterior and posterior skin-flaps; as for controlling hemorrhage, the hands were best; he had not had much experience with the rectal staff.

Discussion of paper by Dr. L. H. Sayre, of New York.

Dr. Springler, of Dresden, remarked that about one-fifth of these cases healed primarily; one-fifth in about three weeks, and one-fifth in about two to three years, and then perhaps would die from the amputation and prolonged drain on the system.

Discussion on aspiration of hip-joint by Dr. Benton.

Dr. Lange, of New York, stated that he thought the conclusions on the subject were rather premature.

The question was asked if the fluid were examined under the microscope for bacilli; also whether the fluid was removed as a curative measure or only to relieve pain.

To the former question Mr. Owen replied it was not, and as to the latter it was both; replying that if you are in doubt as to these cases, put in your trocar and cannula; you can do no harm and you may do good.

In regard to Dr. Garmony's paper, Dr. Burney stated that he had a case of a boy whose skull was fractured, and shortly afterward was taken with maniacal attacks of screaming epilepsy. He was trephined and two buttons of bone were removed; a second operation was performed and the dura mater incised, when immediately a large quantity of cerebro-spinal fluid gushed out, which very much alarmed the speaker; sponges were quickly placed in the cavity and the wound sewed up. Since that time he has gradually improved.

Dr. Manley, of New York, read a paper on a case of

GUN-SHOT WOUND OF THE LARGE INTESTINE, WITH A SUCCESSFUL RESULT BY LAPAROTOMY.

The patient was operated on twice. The speaker considered that opening of the peritoneal cavity of a man was far different to opening that of a woman, and liable to more risks; the breathing of a man is largely abdominal, while that of a woman is almost entirely thoracic; the incision in the man should not be a bit larger

than is necessary, because of his laborious work being liable to produce ventral hernia after recovery. For exploratory operations he made the median incision, but thought there might be exceptions to this rule. In regard to the drainage-tube in these gunshot wounds of the abdomen, he thought there was no need of them when the peritoneal cavity was healthy and laparotomy performed soon after the injury, and although he had put one in in the case spoken of, he should not do it in the next one. Of course there might be exceptions, but he believed the tube was a source of irritation and more liable to produce hernia.

AFTERNOON SESSION.

DR. ROBERT NEWMAN, of New York, read a paper on

THE USE OF THE GALVANO-CAUTERY SOUND,

particularly in hypertrophy of the prostate gland, with report of cases. The application of the cautery, he stated, would depend much on the condition of the patient, but it averaged about from every three to six days; the cautery was not to be red hot, but simply to show a bright light. The apparatus was exhibited to the Section. The advantages claimed are that there is no hemorrhage, the healing is more rapid, and there is no septicæmia. Out of these cases ninety-one per cent. are made comfortable and given a new lease of life.

DR. CARNOCHAN, of New York, presented a remarkable specimen of

BONY UNION OF THE NECK OF THE FEMUR WITHIN THE CAPSULE,

after fracture, occurring in a woman seventy years of age. As she had plenty of means she had every attention. She was kept in her fracture-bed for nine months, rest being the method of treatment. The value of the specimen was very great, especially in courts of law.

DR. F. LEMOYNE, of Pittsburg, presented some drawings of an united fracture of the femur, and history of a successful case in which he had applied his method of treatment, viz.,

DOUBLE SPLICE AND WIRED CLAMPS.

The treatment has been successful in three cases—two of the humerus and this one of the femur. The bone was cut down upon and the fragments found to be overlapping nearly three inches. The ends were sawed off, the upper fragment in the form of a wedge; from the lower one a wedge-shaped piece of bone was removed, so that the upper fragment fitted into it. A hole was drilled in both bones about one and a half inch from the fractured ends. A stiff, flat, steel bar, with a prong at either end, was placed lengthwise on the surface of the bone, so that the prongs were inserted into the holes; a stout piece of wire was then passed around the clamp and femur at either end, and twisted close up, holding the clamp in position. The wires and clamp remained there nine weeks, when the wound was reopened and the clamp removed. The bone was firmly united, but the limb is two and a half inches shorter.

DR. MANLEY, of New York, stated that he had had considerable experience in wiring bones, and thought the bones when lapping very much should be wired at the first; the wires he always left in, as they did no harm. In one case of compound comminuted fracture he had followed this method and secured perfect union.

DR. QUIMBY, of Jersey City, stated that he could hardly approve of this method.

DR. LEMOYNE remarked, that he thought his method was original, and previously everything else had failed, the man having undergone a number of operations prior to his treatment, and all of his cases so treated had met with success; he did not believe in wiring in primary fractures.

DR. GIBSON exhibited some wire extension splints for fractures at or near the joints; he had used them since 1879. They were a modification of the wire splint of Dr. Nathan Smith, and, as one gentleman remarked, seemed like resurrecting him.

DR. MYERS remarked that he thought the day of extension, except in compound fractures, had gone by; he was very well satisfied with plaster-of-Paris, board, or some simple and light dressing.

Several other gentlemen remarked to the same effect.

DR. GIBSON replied that he wished it understood that he did not use this splint in all cases, but for those fractures at or near the joints.

In discussing Dr. Manley's paper, DR. QUIMBY stated that he thought in many cases of wounds the tubes were left in too long. He quoted one case of laparotomy in which no tubes were introduced. Death followed the operation; the wound was reopened, and the peritoneal cavity found perfectly dry.

DR. MANLEY concluded by saying that in ovariotomy, where substances were removed, it was different, but in gunshot wounds he considered the tubes injurious.

SECTION IN MILITARY AND NAVAL SURGERY AND MEDICINE.

THURSDAY, SEPTEMBER 8TH—FOURTH DAY—MORNING SESSION.

DR. J. D. BRYANT, of New York, being absent, his paper, entitled

ON THE CAUSES AND TREATMENT OF ERYSIPELAS,

was read by title, and was by an unanimous vote referred to the Committee on Publication.

A paper by DR. WILLIAM VARIAN, of Titusville, Pa., on the subject of

ETIOLOGY AND TREATMENT OF HOSPITAL GANGRENE DURING THE WAR,

then followed. The author enumerated the symptoms of this disease as observed by himself during the late war, and the causes which were probably concerned in its development. There may be certain atmospheric conditions, such as the prevalence of cold, wet weather, or hot moist weather, with marked electric or barometric oscillations. The influence of bad food, imperfect care, and mental depression acted, the speaker said, as a predisposing cause. The probability of the presence in the atmosphere of some unknown septic poison was discussed at length. A necessary condition for the development of the disease is the existence of a solution of continuity of the cuticle or soft tissues generally; the same may be said of wounds in a state of suppuration and granulation; non-recent wounds being, however, more likely to be attacked. Hospital gangrene is a local, and not a systemic, disease; it develops an auto-generative contagium, which may be spread by atmospheric diffusion, or may be conveyed from patient to patient by the surgeon's hands, instruments, or dressings. That it is a local disease is attested by the fact that it may develop in only one wound upon an individual afflicted with a number of them; a few such cases were observed during the late war by others besides myself.

The subject of treatment was then entered upon. The futility of medicinal treatment was shown, and the complete destruction of the tissues affected was, the author said, essential to successful treatment. These should be boldly removed by the knife, and some caustic thoroughly applied. Success is less dependent upon the nature of the latter than upon its thorough application. In his experience he had found bromine the surest, although the most disagreeable; but nitric acid and the acid nitrate of mercury had also been successfully used. The importance of a supporting treatment, of good food, stimulants, and tonics, to combat the great vital depression which always co-exists was shown. In conclusion, the author remarked that a strict asepsis should eliminate hospital gangrene from the surgery of the future.

Dr. Frederick Hyde, of Syracuse, N. Y., desired to know if the author had met with cases in which the disease had actually been communicated by unclean sponges and dressings; he had himself observed this in a number of instances. An affirmative answer being given,

Dr. Pickett, of Cory, Pa., related his personal experience with hospital gangrene; he had been treated by bromine and cured, but the disease had made such an impression upon him that he was still suffering.

The President, Dr. Smith, asked one of the British members, Dr. Anderson, of the British army, what had been his experience with the disease. The doctor replied that he had never met with it in his hospital experience, whereupon the President congratulated him upon his good fortune.

An interesting paper on

THE ETIOLOGY AND TREATMENT OF CAMP DYSENTERY AND DIARRHŒA,

was read by Dr. Charles W. Buvinger, of Pittsburg, Pa. Camp dysentery and diarrhœa are always the result of a radical change in the manner of living; by the use of bad water from stagnant pools or wells contaminated with organic matters. The use of improperly cooked food, and privations, were important factors. The speaker adverted to the influence of malarial or paludal neighborhoods, and to that of scurvy in their causation.
